

Effect of Gold Content on the Microstructural Evolution of SAC305 Solder Joints Under Isothermal Aging

MIKE POWERS, JIANBIAO PAN, JULIE SILK,
and PATRICK HYLAND

Au over Ni on Cu is a widely used printed circuit board (PCB) surface finish, under bump metallization (UBM), and component lead metallization. It is generally accepted that less than 3 wt.% Au in Sn-Pb solder joints inhibits formation of detrimental intermetallic compounds (IMC). However, the critical limit for Au content in Pb-free solder joints is not well established. Three surface-mount package platforms, one with a matte Sn surface finish and the others with Ni/Au finish, were soldered to Ni/Au-finished PCB using Sn-3.0Ag-0.5Cu (SAC305) solder, in a realistic manufacturing setting. The assembled boards were divided into three groups: one without any thermal treatment, one subjected to isothermal aging at 125°C for 30 days, and the third group aged at 125°C for 56 days. Representative solder joints were cross-sectioned and analyzed using scanning electron microscopy (SEM) and energy-dispersive x-ray spectroscopy (EDX) to investigate the evolution of the solder joint morphology as a function of Au content and isothermal aging. It was found that, if Cu is available to dissolve in the solder joint, the migration of AuSn₄ from the bulk to the interface as a result of thermal aging is mitigated.

Key words: Pb-free solder, isothermal aging, Ni/Au surface finish, Au content, Sn-Ag-Cu, intermetallic compound

INTRODUCTION

Ni/Au over Cu is a popular finish metallization for PCB, UBM, and ball grid array/chip-scale package pads. Ni can be applied to Cu traces and pads via an electrolytic or electroless plating process and serves as a diffusion barrier layer. Au can be deposited by electrolytic, electroless, or an immersion plating process. The function of the Au layer is to protect the Ni layer from oxidation and corrosion, to enhance the wettability of solder to the surface, and in some applications, to improve wire bondability. While a thicker Au layer improves wire bondability, it can also increase the possibility of Au embrittlement in the resulting solder joints. It is generally accepted that less than 3 wt.% Au in Sn-Pb solder joints will inhibit the formation of detrimental

IMCs.^{1,2} However, the critical limit for Au content in Pb-free solder joints is not well established.

By now, the effect of Ni/Au on Sn-Pb solder joint reliability and the mechanism for IMC formation has been established. During the solder reflow process, Au on the PCB pads (and/or on component metallizations) dissolves rapidly into the bulk molten solder and forms needle-like AuSn₄ IMC.³ The AuSn₄ IMC is distributed throughout the bulk solder joint after reflow, and the Ni diffusion barrier reacts with Sn to form a thin Ni₃Sn₄ IMC at the interface. Following thermal aging at over 100°C for several hundred hours, the AuSn₄ migrates to the Ni interface and forms a continuous layer of (Au,Ni)Sn₄ IMC over a Ni₃Sn₄ IMC layer.⁴⁻⁶ The weak interface between (Au,Ni)Sn₄ and Ni₃Sn₄ can lead to brittle failure.⁷ The driving force for the migration of AuSn₄ is a reduction of Gibbs free energy by mixing.⁸ Au seeks Ni so that the AuSn₄ becomes a Ni-saturated (Au,Ni)Sn₄ compound.⁹

However, if the Ni barrier layer is sufficiently thin, then Cu can diffuse through the barrier to the (Au,Ni)Sn₄ interface.¹⁰ In this case, the (Au,Ni)Sn₄ IMC transforms to (Au,Cu,Ni)₆Sn₅.¹¹ Elimination of the brittle layer of (Au,Ni)Sn₄ IMC over the Ni₃Sn₄ layer mitigates crack propagation along the interface. Although a thin Ni diffusion barrier layer produces this benefit, in practice Cu diffusion and oxidation can limit PCB shelf-life and hinder solderability.

The objective of this investigation is to study the morphological effect of increasing amounts of Au in SAC305 Pb-free solder joints between packaged integrated circuit (IC) components and PCBs with Au over Ni finish, and the evolution of the solder joint microstructures under isothermal aging at 125°C. An important aspect of this work is to distinguish between packaged IC platforms that employ a Ni diffusion barrier and those that do not.

EXPERIMENTAL PROCEDURES

Printed circuit assemblies (PCA) were manufactured using a standard surface-mount assembly process in a realistic production environment at Jabil Circuit, San Jose, California. The test vehicle was designed as a six-layer PCB fabricated using Nelco[®] N4000-12 epoxy resin with an electrolytic Au over Ni finish on the Cu traces and pads. The solder paste was SAC305, 217°C melting point, type 3 with no-clean flux and a metal content of 88% by weight. The solder paste stencil was laser-cut from electroformed Ni with a thickness of 0.1 mm and a 1:1 aperture-to-pad ratio. The volume, area, and height of the solder paste on each pad were measured using a Koh Young KY-3030VAL solder paste inspection system. Solder reflow was performed in a Vitronics Soltec XPM2 belt furnace under nitrogen

atmosphere. The reflow temperature profile displayed a maximum heating rate of 3.2°C/s, soak time of 60 s to 120 s between 150°C and 217°C, peak temperature between 235°C and 245°C, time above liquidus of 60 s to 90 s, and maximum cooling rate of 1°C/s to 4°C/s. All of the resulting solder joints were inspected using a Phoenix Nanomex x-ray inspection system to verify joint integrity as-built.

Three packaging platforms, in various sizes and configurations, were soldered to PCBs using two different Au thicknesses (thick and flash). All of the packaged IC components were daisy-chained to facilitate resistance measurements. The Au thickness of the surface finish from random locations on the PCBs and component pads/leads was measured using a CMI XRX series x-ray fluorescence (XRF) system. The QFN platform is a quad flat no-lead packaging technology with a matte Sn finish over Cu pads (i.e., no Ni diffusion barrier). Two QFN package sizes were employed, 5 mm × 5 mm and 6 mm × 6 mm. The TOPS platform is a 10 mm × 10 mm no-lead package with an open-cavity epoxy laminate construction. The pad finish on the TOPS is electrolytic Au over Ni. The FP platform is an open-cavity ceramic package with flat Kovar[®] (ASTM F-15 alloy) leads and an electrolytic Au over Ni finish. The FP packages have two configurations, a 6.4 mm × 6.4 mm footprint with 12 leads and a 10.2 mm × 9.7 mm footprint with 22 leads. Figure 1 shows photographs of the footprints for the components used in this study. The type and thickness of the metallizations on the components and boards are summarized in Table I.

Due to the variation in Au thickness and solder volume at different locations on a particular board, from board to board, and on different component leads, both the average, and the range of solder joint Au content were calculated. It was found that the

Fig. 1. Components used for PCA test vehicle.

Table I. Metallization thickness of components and boards

	Metallization	Thickness
QFN	Matte Sn over Cu pads	–
TOPS	Ni/Au over Cu leads	0.2 μm to 0.3 μm Au over 3 μm to 8 μm Ni
FP	Ni/Au over Kovar leads	1 μm to 2 μm Au over 1 μm to 5 μm Ni
PCB	Ni/Au over Cu traces	Flash Au: 0.08 μm to 0.38 μm Au over 5 μm Ni Thick Au: 2 μm to 2.54 μm Au over 5 μm Ni

Table II. Average and range of Au content in weight percent

	QFN5	QFN6	TOPS	FPI	FPII
Flash Au board					
Average	0.5	0.5	2.5	15.0	11.8
Range	0.3–0.9	0.3–0.9	1.6–3.6	13.0–18.0	10.0–14.0
Thick Au board					
Average	4.2	4.0	5.5	16.0	13.7
Range	3.0–7.0	3.0–7.0	4.0–8.0	14.0–19.0	11.8–16.0

SAC305 solder wetted the sides and tops of Au-plated leads, which served to incrementally increase the gold content of the corresponding solder joints.

The Au content in the solder joints was calculated according to Eq. (1).

$$\text{wt.\% Au} = \frac{\text{Au weight in component} + \text{Au weight in PCB}}{\text{Sn-Ag-Cu weight in paste} + \text{Au weight in component} + \text{Au weight in PCB}}, \quad (1)$$

where the Au weight in component = (area of component lead) \times (Au thickness on component lead) \times (density of Au), the Au weight in PCB = (area of pad) \times (Au thickness on PCB) \times (density of Au), and Sn-Ag-Cu weight in paste = (measured solder paste volume) \times (metal content in volume) \times (density of SAC305). The average and range of Au content in solder joints associated with the various surface-mount package platforms are summarized in Table II. The Au content between these three package platforms on boards with thick or flash Au electroplating varies significantly.

After assembly, one flash Au board and one thick Au board were randomly selected for cross-sectioning and SEM/EDX analysis. This is the control group, since the PCAs did not receive any thermal aging. One group of boards was subjected to isothermal aging at 125°C for 30 days, and another group for 56 days. After isothermal aging, one flash Au board and one thick Au board were randomly selected for cross-sectioning and SEM/EDX analysis. The SEM used in this study was a JEOL JSM-6390 equipped with a Thermo Scientific 6733A EDX.

RESULTS AND DISCUSSION

The evolution of the microstructure for solder joints in this investigation is addressed in two sections, one based on a package substrate finish that does not have a Ni diffusion barrier (i.e., QFN) and

the other that includes a Ni barrier layer in the substrate finish. In both cases, the isothermal aging times are compared as a function of relative Au content in the solder joints.

Cu/Sn-solder-Au/Ni/Cu System (<1 wt.% Au)

An SEM micrograph of an as-built solder joint between a QFN component and a board with a flash Au finish is shown in Fig. 2. The Au content in the solder joint is about 0.9% by weight. The Cu lead of the component has a matte Sn finish. The board finish is Ni/Au. Figure 2 demonstrates that the interfacial IMC on both the component (top of micrograph) and board (bottom of micrograph) sides of the joint is $(\text{Cu,Ni})_6\text{Sn}_5$, although the relative weight percentages of Cu and Ni differ. The Cu concentration is higher and the Ni concentration is lower at the component interface, as would be expected (i.e., QFN has no Ni diffusion barrier). The plethora of small nodular IMCs in the bulk solder is $(\text{Au,Cu})\text{Sn}_4$. Note that the figure annotation 35Cu2-Ni63Sn means 35 wt.% Cu, 2 wt.% Ni, and 63 wt.% Sn, as determined by EDX. It is interesting to note

Fig. 2. SEM micrograph of an as-built solder joint between a QFN component and a board with flash Au finish. The Au content is about 0.9 wt.%.

Fig. 4. SEM micrograph of an aged solder joint between a QFN component and a board with flash Au finish. The Au content is about 0.6 wt.%. The sample was aged at 125°C for 56 days.

Fig. 3. SEM micrograph of an aged solder joint between a QFN component and a board with flash Au finish. The Au content is about 0.6 wt.%. The sample was aged at 125°C for 30 days.

that the interfacial IMC is not Ni_3Sn_4 , as typically reported for the case of Sn-Pb solder without added Cu.^{12,13} The $(\text{Cu},\text{Ni})_6\text{Sn}_5$ IMC is consistent with that reported for the Sn-Ag-Cu case.^{14,15}

Following isothermal aging at 125°C for 30 days, the microstructure of an aged solder joint with low Au content is shown in Fig. 3. The IMC at both the component and board interfaces is $(\text{Cu},\text{Ni},\text{Au})_6\text{Sn}_5$. The IMC in the bulk solder joint is AgSn, which is not consistent with the Ag_3Sn typically reported by others.^{13,16} This could be the result of the EDX detecting Sn outside the window, due to the small size of the IMCs analyzed (about 1 μm to 2 μm). Figure 3 clearly shows that, after thermal aging, Au in the bulk solder of the as-built sample diffused to the interfaces, forming $(\text{Cu},\text{Ni},\text{Au})_6\text{Sn}_5$. It is noteworthy that AuSn_4 was not observed at the interfaces or in the bulk solder after aging. This is probably due to the low Au content (<1 wt.%) in the

solder joint. After aging for 56 days, no significant changes were observed in the IMC composition compared with the sample aged for 30 days, as shown in Fig. 4. However, the mean IMC thickness increased from 2.4 μm after reflow to 4.7 μm after 30 days aging and 6.1 μm after 56 days aging at the component interface. At the board interface, the mean IMC thickness increased from 1.6 μm after reflow to 3.0 μm after 30 days aging and 7.1 μm after 56 days aging.

Cu/Sn-Solder-Au/Ni/Cu System (3 wt.% to 7 wt.% Au)

An SEM micrograph of an as-built solder joint between a QFN component and a board with thick Au finish is shown in Fig. 5. The Au content in the solder joint is about 6.3 wt.%. The IMCs in the bulk solder joint consist of large plate-like AuSn_4 and small nodular AgSn. The IMCs at the interface near the component and board side are $(\text{Cu},\text{Ni},\text{Au})_6\text{Sn}_5$, although the Cu concentration is higher on the component side and the Ni concentration is higher on the board side. Compared with the as-built samples with <1 wt.% Au, as-built solder joints in this group manifested AuSn_4 in the bulk solder as well as Au in the interfacial IMCs. It is important to note that the $(\text{Cu},\text{Ni},\text{Au})_6\text{Sn}_5$ IMC was identified in some samples while $(\text{Cu},\text{Ni},\text{Au})\text{Sn}$ IMC was identified in other samples.

After thermal aging at 125°C for 30 days, the IMC at the interface near both the component and board sides was $(\text{Cu},\text{Ni},\text{Au})_6\text{Sn}_5$, but the weight percentages of Cu and Ni were not identical (Fig. 6). It is clear that small AuSn_4 plates in the bulk solder of the as-built sample coalesced into larger AuSn_4 IMC as a result of aging. The driving force for this coarsening behavior is the energy reduction associated with a lower surface-area-to-volume ratio. After thermal aging for 56 days the composition of

Fig. 5. SEM micrograph of an as-built solder joint between a QFN component and a board with thick Au finish. The Au content is about 6.3 wt.%.

Fig. 7. SEM micrograph of an aged solder joint between a QFN component and a board with thick Au finish. The Au content is about 5.6 wt.%. The sample was aged at 125°C for 56 days.

Fig. 6. SEM micrograph of an aged solder joint between a QFN component and a board with thick Au finish. The Au content is about 5.6 wt.%. The sample was aged at 125°C for 30 days.

Fig. 8. SEM micrograph of an as-built solder joint between a TOPS component and a board with flash Au finish. The Au content is about 3.0 wt.%.

the IMCs was essentially the same, as shown in Fig. 7. However, the mean IMC thickness at the interfaces increased from 2.3 μm after reflow to 3.5 μm after 30 days aging and 4.8 μm after 56 days aging at the component interface, while at the board interface it increased from 1.8 μm after reflow to 2.8 μm after 30 days aging and 5.9 μm after 56 days aging. It should be pointed out that $(\text{Au},\text{Ni})\text{Sn}_4$ over Ni_3Sn_4 was not observed after thermal aging, as commonly occurs in the Sn-Pb case. This result is consistent with the conclusion of Ho et al.⁷ that the presence of sufficient Cu in the melt precludes redeposition of the interfacial $(\text{Au},\text{Ni})\text{Sn}_4$ IMC layer during thermal aging.

Cu/Ni/Au-Solder-Au/Ni/Cu System (2 wt.% to 3 wt.% Au)

An SEM micrograph of an as-built solder joint between a TOPS component and a board with flash

Au finish is shown in Fig. 8. The Au content in the solder joint is about 3.0 wt.%. The metallization on the Cu leads, as well as the PCB finish, is Au over Ni. The IMC at both the component and board interfaces is $(\text{Ni},\text{Cu},\text{Au})_3\text{Sn}_4$. The IMC observed in the bulk solder consists of AuSn_4 and AgSn .

An SEM micrograph of a solder joint aged for 30 days is shown in Fig. 9. There are clearly two layers of IMC at the interface near the component and board side of the solder joint. The IMC adjacent to the Ni layer is $(\text{Ni},\text{Cu},\text{Au})_3\text{Sn}_4$, while the IMC near the bulk solder side is $(\text{Au},\text{Ni})\text{Sn}_4$. The IMCs in the bulk solder are plate-like $(\text{Au},\text{Ni})\text{Sn}_4$ and small nodules of AgSn . It appears that the small AuSn_4 IMCs in the bulk solder of the as-built sample coalesced into larger $(\text{Au},\text{Ni})\text{Sn}_4$ IMCs as a result of thermal aging. Following thermal aging for 56 days, no significant change in IMC composition was observed, except that the mean thickness of interfacial

Fig. 9. SEM micrograph of an aged solder joint between a TOPS component and a board with flash Au finish. The Au content is about 2.4 wt.%. The sample was aged at 125°C for 30 days.

IMC layers increased from 2.6 μm after reflow to 4.5 μm after 30 days aging and about 7 μm after 56 days aging, at both interfaces.

Cu/Ni/Au-Solder-Au/Ni/Cu System (4 wt.% to 7 wt.% Au)

An SEM micrograph of an as-built solder joint between a TOPS component and a board with thick Au finish is shown in Fig. 10. The Au content in the solder joint is about 5.8% by weight. The IMC at the interface on the board side is $(\text{Ni,Cu,Au})_3\text{Sn}_4$ adjacent to the Ni layer with a layer of $(\text{Au,Ni,Cu})\text{Sn}_4$ above it. It is difficult to distinguish separate IMC layers at the component side of the joint. The IMC on the component side is $(\text{Ni,Cu,Au})\text{Sn}$, which could be a mix of $(\text{Ni,Cu,Au})_3\text{Sn}_4$ and $(\text{Au,Ni,Cu})\text{Sn}_4$. The IMC in the bulk solder is plate-like AuSn_4 and nodular AgSn_2 . As with the case of the AgSn_2 IMC identified in previous figures, the AgSn_2 here may actually be Ag_3Sn , as a result of the EDX detecting Sn outside the window due to the small size of the IMCs analyzed.

The microstructure after thermal aging for 30 days is shown in Fig. 11. The IMC adjacent to the Ni layer is $(\text{Ni,Cu,Au})\text{Sn}$ and near the bulk solder side is $(\text{Au,Ni})\text{Sn}_4$. The mean IMC thickness grew from 1.9 μm to 8.6 μm compared with the as-built samples. The IMCs in the bulk solder changed from AuSn_4 to $(\text{Au,Ni})\text{Sn}_4$ as a result of aging. After thermal aging for 56 days, there was no significant change in the composition of the IMCs, but the mean IMC thickness at both interfaces increased to approximately 9.5 μm .

Kovar/Ni/Au-Solder-Au/Ni/Cu System (> 10 wt.% Au)

An SEM micrograph of an as-built solder joint between an FP component and a board with flash Au finish is shown in Fig. 12. XRF measurements of

Fig. 10. SEM micrograph of an as-built solder joint between a TOPS component and a board with thick Au finish. The Au content is about 5.8 wt.%.

Fig. 11. SEM micrograph of an aged solder joint between a TOPS component and a board with thick Au finish. The Au content is about 7.1 wt.%. The sample was aged at 125°C for 30 days.

the Au plating on the leads of these components revealed that the Au thickness was significantly higher compared with the other component platforms (1 μm to 2 μm). As a result, the Au content in the solder joint is about 14.4 wt.% and the entire joint is dominated by $(\text{Au,Ni})\text{Sn}_4$. After thermal aging for up to 56 days, there was no significant change in the composition or morphology of the IMC.

An as-built solder joint between an FP component and a board with thick Au finish is shown in Fig. 13. The Au content in this solder joint is about 15 wt.%, and it is clear that $(\text{Au,Ni})\text{Sn}_4$ dominates the entire joint. The fracture in the solder joint was discovered immediately after assembly. The resistance measurements on the daisy-chained solder joints confirmed that opens occurred on many FP components mounted on thick Au boards. The reliability of such solder joints is very poor, as reported in other

Fig. 12. SEM micrograph of an as-built solder joint between an FP component and a board with flash Au finish. The Au content is about 14.4 wt.%.

Fig. 14. SEM micrograph of a solder joint between an FP component and a board with thick Au finish. The Au content is about 15.8 wt.%. The sample was aged at 125°C for 30 days.

Fig. 13. SEM micrograph of an as-built solder joint between an FP component and a board with thick Au finish. The Au content is about 15 wt.%.

publications by this group.^{17,18} After thermal aging for up to 56 days, no major change in the IMCs was observed, except that the cracks in the solder joints grew larger (Fig. 14). With reference to Fig. 14, the Ag_3Sn IMC is identified in the bulk of the aged solder joint. This lends credence to the possibility that the AgSn and AgSn_2 IMCs identified in previous figures are actually Ag_3Sn .

CONCLUSIONS

Packaged IC components were soldered to PCBs with a Ni/Au finish using SAC305 Pb-free solder in a “real” manufacturing environment. Some of the resulting PCAs were isothermally aged at 125°C for 30 days or 56 days, and the evolution of the resulting morphologies was investigated using SEM/EDX. From the experimental results obtained, the following conclusions can be drawn:

- When the Au content is less than 1 wt.%, AuSn_4 IMCs are not observed in the solder joint either before or after thermal aging.
- When Cu from the component is available to dissolve in the solder joint, the resulting interfacial IMCs are dominated by Cu and Sn. The primary interfacial IMC observed is $(\text{Cu}, \text{Ni})_6\text{Sn}_5$ or $(\text{Cu}, \text{Ni}, \text{Au})_6\text{Sn}_5$.
- If Cu is available to dissolve in the solder joint, $(\text{Au}, \text{Ni})\text{Sn}_4$ does not redeposit at the interface as a result of thermal aging.
- If Ni barrier layers are present on both the board and component sides of the interface, Cu diffusion from the substrate is mitigated and only the Cu from the Sn-Ag-Cu solder is available to the joint. In this case, the interfacial IMCs are dominated by Ni and Sn. The primary interfacial IMC observed is $(\text{Ni}, \text{Cu})_3\text{Sn}_4$ or $(\text{Ni}, \text{Cu}, \text{Au})_3\text{Sn}_4$.
- If Ni layers are present on both the board and component sides of the interface, availability of Cu in the joint is limited and $(\text{Au}, \text{Ni})\text{Sn}_4$ migrates to the interfacial IMC layer as a result of thermal aging.
- In cases where the Au content is high enough to drive formation of AuSn_4 in as-built solder joints, thermal aging drives the coalescence of small AuSn_4 plates in the bulk solder to form larger AuSn_4 IMCs, in order to decrease the surface-area-to-volume ratio.
- If the Au content is over 10 wt.%, the entire solder joint is dominated by the brittle $(\text{Au}, \text{Ni})\text{Sn}_4$ IMC. Future work will study the impact of multiple reflow cycles on IMC thickness and the kinetics of IMC formation, as well as the formation of voids in the bulk solder joint.

ACKNOWLEDGEMENTS

J.P. is grateful to Agilent for funding this project during his sabbatical leave. The authors want to thank Sundar Sethuraman of Jabil for assembling

the PCAs and Prof. Richard Savage at Cal Poly for assistance in SEM analysis.
