The Economics of Enforcement: The Case of OSHA

Michael L. Marlow

A model of enforcement is developed that determines the impacts of OSHA actions on regulated parties. This model analyzes the effect of decision procedures developed by OSHA to enforce the law and their effects on resource allocation within the firm. It is concluded that the impacts from both the initial inspection and reinspection programs on the resource allocations of firms have likely been insignificantly different from zero. If OSHA is to increase the allocation of injury control resources of firms through its enforcement program, it must increase the costs of noncompliance that it imposes on firms.

INTRODUCTION

The Occupational Safety and Health (OSH) Act of 1970 provides for safety regulation of 5 million workplaces. This law is one of the many new types of regulation introduced in the 1970s to regulate the economy on a nationwide basis. A major problem that hinders policy makers is the effective enforcement of such regulation. Enforcement of the act is the responsibility of the Occupational Safety and Health Administration (OSHA).

Previous research has concluded that OSHA has not exerted a significant impact on regulated firms. Chelius (1974) and Smith (1975) find that OSHA has not exerted a significant impact on injury rates, and Chelius concludes that even though injury rates decreased after the OSH Act, these decreases are not related to OSHA but rather to drops in business activity and young worker employment. Gleason and Barnum (1975) find that the costs imposed on firms for noncompliance are trivial in comparison with the opportunity costs of investments unrelated to the correction of violations. Viscusi (1979) concludes that OSHA has failed to exert a significant impact on the actual or planned safety investments of firms.

This paper examines the powers of OSHA by developing a model of enforcement that details the impact OSHA can exert on firms and yields insights into this agency's historical progress toward legislated goals. It differs from previous studies in the following ways. First, this paper examines the effectiveness of initial and reinspection programs whereas in the study of Gleason and Barnum (1975), for example, only initial inspections are considered. Second, this model confines violations to those that are penalized, not total violations. When a firm expects with great certainty to be found in violation but not penalized, it has less incentive to consider correction. Third, this paper does not consider the impact of OSHA on injury rates. To the extent that injuries are the result of both “unsafe” job habits and engineering controls, OSHA's impact on injuries will likely be insignificant from zero since it does not control the job habits of workers. Fourth, this paper analyzes enforcement on the state and national level. One of the characteristic problems with previous research is that analysis of enforcement parameters based on aggregate data does not provide information on how close these values are to the parameter values derived on a state basis. This paper offers insights into the issue of whether previous research provides both reliable and general results.

Since the present study most closely resembles the study by Viscusi (1979), a separate and detailed discussion of the important differences between these two is presented here. One difference is that Viscusi assumes workers desire constant work place quality, generating the result that workers cannot increase their real wages by increasing their personal level of control effort. On the contrary, we argue that if OSHA exerts a significant effect on firms, it causes workers to become more safety-conscious since em-

---

1 See U.S. Department of Commerce (1977). Only recently, and very rarely, have the courts held firms liable for unsafe acts by employees. See, for example, Brennan v. OSHRC and Conrad Precision Industries (2 OSHC 1137).
employers would attach relatively higher premiums to personal safety control. In addition, if OSHA were able to increase information on risk to workers, OSHA would have the power to increase both the market wages and the costs of firms. The opposite conclusion is found by Viscusi: as OSHA increases the control efforts of firms, workers decrease their level of personal control. This conclusion leads Viscusi to the following policy consideration: there is a danger that stringent enforcement may increase work hazards because of decreases in the personal control efforts of workers. This paper’s conclusion is quite different: if OSHA is to increase injury control, it must increase its level of enforcement.

The other major difference between this paper and Viscusi concerns the testing of the enforcement model. Viscusi examines the impact of certain OSHA penalty and inspection variables on investment in control equipment by firms and worker injury rates. No significant relationship is found between these variables after it is recognized that OSHA’s historical use of enforcement sanctions have caused trivial costs to firms. This paper recognizes that previous studies have found trivial costs to firms and addresses the following questions. How may OSHA affect the compliance of regulated parties? Has OSHA affected certain segments of the nation? To what level must sanctions be raised to affect compliance significantly?

**ENFORCEMENT MODEL**

Effective enforcement of rules relies on both information gathering and penalizing activities. Information gathering is the acquisition of information on the compliance decisions of firms. Searches may take many forms: inspection, monitoring activity, and complaint information from outside parties. The principal means by which OSHA gathers information on compliance activity is through work place inspections. During fiscal 1977 OSHA conducted 196,078 inspections. Penalties for detected violations are usually of two types: nonserious and serious. Each nonserious violation, with a civil penalty of up to $1,000, has a direct relationship to job safety and health but probably would not cause death or serious injury. A serious violation carries a significant probability that death or serious physical harm could result and assumes the employer knew, or should have known of, the violation.

Together the information gathering and penalizing powers of agencies lead to potential costs to violators. Both activities are needed to generate an expected loss for a firm out of compliance with various rules. For example, if a regulated firm expects with great certainty to be found in violation but not penalized for a violation, it will have less incentive to correct the violation. When applied in combination, the inspection and penalizing activities determine whether it “pays” for firms to comply with rules.

A description of the cost function for the firm in some state of noncompliance is

\[ C_i = C(x, y, \lambda, \pi, \rho) \]  

where

- \( C_i \) = expected cost in dollars for violation of rule \( i \), for \( i = 1, 2, \ldots, \eta \)
- \( x \) = probability that OSHA acquired information on compliance for all \( \eta \) rules
- \( y_i \) = penalty in dollars for violation of rule \( i \), for \( i = 1, 2, \ldots, \eta \)
- \( \lambda_i \) = percentage of inspections that penalize violations of rule \( i \), for \( i = 1, 2, \ldots, \eta \)
- \( \Pi_i \) = percentage of inspections that penalize violations of at least one rule
- \( \rho_i \) = cost in dollars associated with continued violations of rule \( i \), apart from penalties, for \( i = 1, 2, \ldots, \eta \).

The first four arguments are called policy parameters because they represent values determined by OSHA, which applies its discretionary enforcement power to influence the expected costs of noncompliance for parties with individual rules through applications of these policy parameters. The remaining arguments are called cost parameters because they measure all other costs not directly related to enforcement.

All four types of policy parameters exert positive effects on the expected costs of noncompliance for the firm. Parameter \( x \) reflects the frequency aspect of inspections; the more inspections conducted, the more firms may expect to be found in violation. Parameters \( \lambda_i \) measure one aspect of the intensity characteristic of inspections; the greater the value of all \( \lambda_i \), the greater the potential cost from violation of rule \( i \). Parameter \( \pi \) represents the rate of penalizing all violations of rules by OSHA during inspections. Both frequency and intensity characteristics are allowed for. The remaining types of policy parameters are the
potential penalties firms face for specific violations of rule $i$ observed during inspections. Values of $y_i$ represent the intensity characteristics of penalizing activity, while frequency aspects are displayed in $\lambda_i$.

Cost parameters $\rho_i$ represent all other costs that may be incurred by a firm subject to inspection. While these parameters may represent many different types of costs, we confine our discussion to the impact of inspection on workers' wages. While workers are considered safety-conscious, they do not possess perfect information on the various risk characteristics associated with alternative employments, and market wages do not reflect perfect compensation for occupational risk. OSHA may increase information on risk to workers through its identification of noncomplying firms, which would increase market wages and the costs of the firm as well. But the degree of identification depends on the characteristics of the rule set that OSHA enforces on firms. There is evidence that OSHA's enforcement program is not aimed at disseminating information on previously unperceived risks to workers and that consequently it has not been successful in increasing worker's compensation for previously uncompensated risk. Owing to the probable trivial impact on market wages exerted by OSHA, the effect of all $\rho_i$ on the costs of noncompliance is assumed to be positive and constant.

The loss function for the regulated firm is defined as

$$E(L) = \sum_{i=1}^{\eta} x_i y_i \rho_i$$  \hspace{1cm} (2)

where $i = 1, 2, \cdots, \eta$ denotes the complete set of rules. This function utilizes all the policy parameters in equation (1) to determine the relevant characteristics of the incentive structure facing firms for compliance with rules. This loss function has several interesting properties regarding the effectiveness of enforcement activity on the compliance decisions of firms. First, not only the absolute level of penalty imposition defines the expected costs of violations; the frequency and intensity characteristics together determine the value of the loss potential. Second, firms must be cited and penalized for violations to affect the costs of their noncompliance. For example, if OSHA observed, but not penalized, violations of rule $i$, it would have a trivial impact on the preregulatory costs of firms for not adopting rule $i$.

The loss function in equation (2) defines the expected loss facing firms in noncompliance in a time period that had not been previously inspected in a given jurisdiction. It is this cost that firms weigh against the returns from alternative investments. Assume there is an alternative investment the size of the outlay necessary for compliance with OSHA rules in a given period. If the return on this alternative investment is greater than $E(L)$ in the same period, the firm does not invest in corrective activity. But if $E(L)$ is greater than the alternative return, the firm does invest in corrective activity. If a firm is inspected in the policy period, the penalties $y_i$ are the expected costs of noncompliance with each penalized violation.

### THE ENFORCEMENT PROGRAMS OF OSHA

#### The Initial Inspection Program

The value of $E(L)$ is estimated in the following manner.\(^7\) Fiscal 1977 is the policy period within which estimates are made. The probability of initial inspection $\alpha$ is estimated by dividing the number of initial inspections by the number of regulated firms. Initial inspections are inspections in the policy period that are not follow-ups of previous inspections in the same policy period. Violations are of two types: serious and nonserious. The percentage of detected violations that are serious and fined is the proxy for $\lambda_1$, the percentage of penalized violations that are serious. A similar estimate is made for penalized nonserious violations $\lambda_2$. The sum of $\lambda_1$ and $\lambda_2$ is unity. Average penalties for serious and nonserious violations $\lambda_1$ and $\lambda_2$ are estimated by dividing total penalties by the number of violations with penalties.

The percentage of initial inspections that penalize violations $\Pi$ is estimated by the percentage of all inspections that penalize violations.

Ideally $t +$ expected loss in equation (2) would be estimated on an industry basis since enforcement levels can be expected to be related to risk levels. Unfortunately such data are not available; rather, such estimates are made on both the state and national levels. Table 1 displays both high and low values for each parameter on the state level and the standard deviation for each parameter. The mean shown is the national mean. From Tchebysheff's inequality, the probability of drawing a sample observation whose value is more than 3 standard

</table>

The deviations away from the mean is 0.0027. In terms of the loss parameters $E(L)$ this corresponds to a limit of $-12.42$ to $20.22$. These estimates suggest that the likely enforcement impact from OSHA on firms is insignificant from zero, so we argue that the national estimates are both reliable and general. This allows us to carry the rest of the discussion in terms of the national estimates.

During fiscal 1977 the initial inspection rate was 3.7, estimates applied to approximately 96 percent of all firms. A firm that had not been initially inspected in fiscal 1977 and was in noncompliance could expect a cost of $3.90 for noncompliance. This implies that an investment in correction yielded a return of $3.90 to the firm that had not been initially inspected. In 1974 the National Association of Manufacturers surveyed its members as to the size of the investment necessary to correct all their violations.\(^8\) Average estimates ranged from $35,000 for firms with 100 or fewer employees to over $4.5 million for those with more than 5000 employees. With the lower estimate of $35,000, a return of $3.90 was associated with a return of 0.01 percent on an investment in correction in fiscal 1977. An alternative investment that yielded a return of 7 percent, for example, would have generated $2450 in revenue to the firm. The data in Table 1 indicate that firms in noncompliance and not initially inspected during fiscal 1977 were likely to have chosen alternative investments as long as correction investments were yielding noncompetitive rates of return.

If a firm was inspected once in any of the policy periods, the penalties would become the expected costs for each violation cited and penalized. By multiplying the average number of violations per initial inspection by the penalty, an estimate of the average cost of an initial inspection is made. This cost would have applied to approximately 4 percent of all firms in fiscal 1977. The average number of serious violations with penalties per initial inspection was 0.19 in fiscal 1977; the average number of nonserious violations with penalties per initial inspection was 0.44; the estimate of the average costs of initial inspections was $103.26. The imposition of this cost would have been considered trivial by firms in this category faced with the alternative of an investment unrelated to correction. The initial inspection program of OSHA had the likely effect of exerting an insignificant from zero impact on the resource allocation of firms inspected once during fiscal 1977 since the initial inspection program produced insufficient incentives for increasing firms' control efforts.

The Reinspection Program

OSHA also enforces the OSH Act through the reinspection of firms previously determined out of compliance. An estimate is made of $E_R(L)$, the expected cost of continued noncompliance for firms not reinspected and not correcting violations detected during initial inspections. This cost is estimated by redefining the policy parameters in equation (2) to correspond to OSHA's reinspection program. The subscript $R$ will denote this correspondence.

The values of $\gamma_R$, $\alpha_R$, and $\Pi_R$ remain unchanged from their initial counterparts in Table 1. Unfortunately, data are unavailable to estimate new values for these parameters in relation to the reinspection program of OSHA. The use of the initial values of the parameters $\gamma_i$ and $\alpha_i$ probably produces underestimates for the true values of these parameters since it is likely that inspectors would cite and penalize continued violations detected during the reinspections more frequently and severely than those de-

\(^8\) See Occupational Hazards (1974, p. 8).
ected during the initial inspection. The use of $\lambda_1$ probably produces an underestimate of $\lambda_{R1}$ since reinspections are to focus on the serious violations of initial inspections. Consequently, $\lambda_2$ is probably an overestimate of $\lambda_{R2}$. The use of $\gamma_1$ probably produces an underestimate of $\gamma_R$ since it is likely that inspectors propose higher penalties for continued violations. The consequence of using $\Pi$ as a proxy of $\Pi_R$ is indeterminate since there are no data on the relative differences in compliance rates between the two types of inspections. Still the estimates of $E_M(L)$ provide information on the costs of continued violations for firms and indicate whether sufficient incentives exist for the correction of violations cited and penalized previously by OSHA in the same policy period. The probability of reinspection $\alpha_R$ is estimated by dividing the number of reinspections by the number of initial inspections. The size of the standard deviation of $E_M(L)$ allows us to carry out this discussion on the national level.

Table 1 displays the reinspection policy parameters and the estimates of $E_M(L)$. The percentage of initial inspections followed by reinspections in fiscal 1977 was 19, implying that roughly 1 percent of all firms were reinspected during this year. With an estimate of $35,000 for the necessary investment in correction, a return of $20.06 in fiscal 1977 is associated with a return of 0.06 percent on an investment in correction. On the other hand, an alternative investment yielding a return of 7 percent generates $2,450 in revenue to the firm. The data in Table 2 indicate that firms that were initially inspected but not reinspected were likely to have chosen alternative investments since investments in correction yielded noncompetitive rates of return. The reinspection program had the likely effect of exerting an insignificant from zero impact upon the resource allocations of firms that were initially inspected but not reinspected during this period.

If a firm is reinspected, the penalties $\gamma_R$ become the expected costs for each violation cited and penalized. By multiplying the average number of violations per reinspection by the average penalty, the cost of reinspections is estimated. This cost applies to the 1 percent of all firms that experienced reinspections in each period. Because there are no data on the average number of violations and average penalties per reinspection, the initial inspection estimates of the previous section are used. The average cost of reinspection in fiscal 1977 was $103.26, amounting to a return of 0.34 percent on an investment in correction of $15,000 and representing a noncompetitive rate of return to the firm. The reinspection program of OSHA exerted an insignificant from zero impact on the resource allocations of firms reinspected once during this period.

A Regression Analysis of Noncompliance

Regression analysis tests the direction of the relationship between noncompliance and the employment of enforcement parameters by OSHA. An obvious problem is the selection of the appropriate definition of noncompliance. An extreme definition would be one or more violations of the entire set of standards; noncompliance is a zero-one decision and probably every regulated firm would be defined in noncompliance. On the other hand, noncompliance can be viewed as a problem of degree, in which degrees of noncompliance are determined by the vigor of the enforcement program and noncompliance is defined by adherence to standards and is also influenced by discretionary authority. We use $\Pi$ defined above as a measure of noncompliance since it allows OSHA to interpret noncompliance continuously and is expected to exhibit a relationship to its employment of enforcement parameters.

The following estimate is obtained by ordinary least-squares using data from the 50 states in fiscal 1977:

$$
\Pi = 0.107 + 0.839x + 0.323z + 0.004y_1 + 0.002y_2
$$

$$
(0.977) (2.20)* (1.62)** (2.14)* (1.56)**
$$

$$
(t \text{ statistic})
$$

$$
R^2 = 0.23
$$

$$
F(4, 47) = 3.59**.
$$

The abbreviations for each of the parameters are defined above and one and two asterisks refer to confidence levels of 95 and 90 percent, respectively. Noncompliance $\Pi$ measures the rate of noncompliance that is a joint probability (i.e., the probability of being initially inspected and being penalized, given initial inspection $l$). All the enforcement parameters exert a positive impact on noncompliance, which reinforces the definition of noncompliance as a measure of enforcement vigor. This implies that in jurisdictions where OSHA cites a relatively high percentage of firms for noncompliance, they are more apt to employ a relatively high use of economic sanctions, and their employment of enforcement
parameters is in the proper direction, consistent with the definition of noncompliance.

CONCLUSION
The examination of the OSHA enforcement program indicates that OSHA has not been successful in achieving its goal of increased work place protection. Impacts from both the initial inspection and reinspection programs on the resource allocations of firms have likely been insignificant from zero. Analysis of the data on the national level leads to reliable and general results with regard to the estimates on the state level. Although the regression analysis indicates that the employment of enforcement parameters is positively related to noncompliance, the impacts from the initial inspection and reinspection programs are too weak to significantly increase the compliance of firms. If OSHA is to increase the injury control resources of firms above that generated in the private market, it must increase the costs of noncompliance to the point of equality with the rates of return on alternative investments. As the model of enforcement indicates, the goal of increased work place protection requires increases in the employment of enforcement parameters.

Our major conclusion and that of previous studies is that the enforcement program of OSHA has not produced additional compliance by firms. Weidenbaum and Defina (1978) find that the compliance costs resulting from OSHA regulation were $3.2 billion in 1976. At first this appears as evidence that OSHA has exerted a significant impact upon the compliance of firms, but in perspective this compliance cost averages only $640 per investment expenditure by each of the approximately 5 million firms under regulation by OSHA.11 This expenditure appears very small but may, be explained by considering that firms invested in occupational injury control long before the arrival of OSHA. Since potential hazards cost the firm, among many other items, lost production and risk compensation to workers, it is in the interest of the firm to invest in injury control equipment. Even without OSHA, changes in worker characteristics, firm output, production methods, and depreciation of existing equipment would generate investment expenditures by firms.12

Two limitations of this study and their implications for public policy will now be addressed. First, the analysis is limited by the level of the data. If OSHA attempts to limit their enforcement effort to a small group of firms, it is possible for this group that OSHA has exerted a significant impact upon injury control decisions.13 Such a subset of firms may be selected owing to their relatively high injury rates. Given its limited budget, OSHA may be able to exert a significant impact on these firms by concentrating its enforcement resources on a select group of them. In this case OSHA may be merely acting in a rational manner to make the best use of its limited budget. Second, it is not clear that it is in the interest of society for OSHA to increase significantly the costs of noncompliance that it imposes on firms. At the macroeconomic level such actions may lead to increased product prices and force certain firms out of business. Such price and unemployment increases need be analyzed as costs to society of regulation and be compared with the projected benefits from the government program.

The author would like to thank Paul B. Downing and the anonymous referees for helpful comments.

REFERENCES

11 See Office of the President (1973).
12 Supporting evidence of this explanation is that no relationship between OSHA activity and the investment behavior of firms has been found (Viscusi 1979).
13 This approach, used by Smith (1975), analyzes the Target Industry Program (TIP) of OSHA. No significant impact on injury rates was found. Since analysis of injury rate changes is an indirect test of the effectiveness of enforcement, an examination of noncompliance costs in TIP would prove useful in future research.
