SUMMARY

Magnetite (\(\text{Fe}_3\text{O}_4\)) crystals produced by two strains of cultured vibrioid magnetotactic bacteria were studied by high-resolution transmission electron microscopy (HRTEM). Both magnetotactic strains were characterized by single chains of magnetite crystals aligned along the long axes of the cells. The strains, designated as MV-2 and MV-4, produced crystals that differed markedly in size and morphology. Crystals present in MV-4 cells were generally larger than those in MV-2 cells and displayed significantly smaller aspect ratios. Crystallographic analysis of the magnetosomes of MV-2 revealed an elongated hexagonal habit based on a prism of \(\{110\}\) faces capped by \(\{111\}\) faces. The axis of elongation was parallel to the \(\langle 111\rangle\) direction. This morphology closely resembles the crystal shape of magnetosomes in a previously described vibrioid species MV-1. In contrast, magnetosomes of MV-4 possessed a cubo-octahedral morphology which was modified by a small elongation along the \(\langle 211\rangle\) direction. Although this morphology has not previously been observed in magnetotactic bacteria, it appears to be intermediate between the regular cubo-octahedral shape of magnetosomes in the cultured species \(\text{Aquaspirillum magnetotacticum}\) and the extensively elongated cubo-octahedral crystals of a previously studied uncultured ovoid-shaped magnetotactic bacterium. The results support the proposal that the crystal morphologies of bacterial magnetite are strain specific.

1. INTRODUCTION

Although the existence of magnetotactic bacteria has been recognized for over 15 years (Blakemore 1975; Blakemore et al. 1980), it is only recently that several new species and strains have been isolated in pure culture (Bazylinski et al. 1988; Matsunaga et al. 1991; Schleifer et al. 1991): these include bacteria with spirilloid and vibrioid morphologies. A coccoid-shaped bacterium has also been successfully maintained in enrichment (Moench 1988) and pure (Meldrum et al. 1993) cultures. The isolation of new magnetotactic bacterial strains is essential for the investigation of the cellular properties of these unusual organisms as well as the elucidation of the magnetic and structural aspects of iron biomineralization processes in bacteria. In this regard, at least three distinct types of crystal morphology have been observed in magnetotactic bacteria containing magnetite (\(\text{Fe}_3\text{O}_4\)) particles (Mann & Frankel 1989). These include isotropic cubo-octahedral particles (Mann et al. 1984a), elongated cubo-octahedral crystals (Mann et al. 1987a b), and elongated hexagonal prisms (Matsuda et al. 1983; Mann et al. 1984b; Sparks et al. 1990). The latter have variations in the number and type of truncated faces but appear to be bacterial strain specific. Recently, we have shown that changes in the chemical conditions of the culture medium can result in minor modifications in the crystal morphology of magnetosomes in the cultured coccus, strain MC-1 (Meldrum et al. 1993). In this paper, we use high-resolution transmission electron microscopy (HRTEM) to characterize the morphological and structural features of magnetite crystals produced by two newly cultured, previously undescribed, vibrioid magnetotactic bacterial strains. Our results show that although both strains are vibrioid in cellular morphology, the associated magnetosomes are different in shape and size, suggesting that the biomineralization of intracellular magnetite in these two organisms involves biochemical processes that are strain- and possibly species specific.

2. MATERIALS AND METHODS

Two magnetotactic bacterial strains were studied. The first, designated strain MV-2, is vibrioid-to-helicoid in morphology, and was isolated from water collected from the Petaquamscutt Estuary, Rhode Island, U.S.A. Cells of this strain are Gram-negative and motile by means of a single polar flagellum. It appears identical to strain MV-1 (Bazylinski et al. 1980) based on phylogenetic analysis of their

Small subunit ribosomal RNA sequences (DeLong et al. 1993). It is probable, therefore, that strains MV-1 and MV-2 are the same species. The second, designated strain MV-4, is also vibrioid-to-helicoid in morphology and was isolated from mud and water from School Street Marsh, Woods Hole, Massachusetts, U.S.A. Cells of strain MV-4 are Gram-negative and bipolarly flagellated.

Both strains were grown in semi-solid medium media (D. A. Bazylinski, unpublished data) under different physiological conditions. Strain MV-2 was grown under chemoautothrophic conditions in an inorganic oxygen-sulphide double gradient medium. Cells of strain MV-4, which did not grow in the presence of sulphide, were also grown under these conditions in an inorganic medium with thiosulphate as the energy source and under chemoheterotrophic conditions with succinate as the carbon and presumed energy source. Both strains were grown until microaerophilic bands of cells formed in the culture tubes. Cells were removed from the cultures with sterile syringes.

Electron microscopic (EM) studies of intact cells were done using a JEOL 2000FX transmission electron microscope (TEM), fitted with a Link windowless elemental dispersive X-ray (EDX) detector and operating at 200 kV. Statistical data on crystal sizes and frequency were obtained from a population of 100 cells of strain MV-2 and 85 cells of strain MV-4. Over 200 crystals were measured for each strain. Sample grids containing air-dried MV-4 cells were treated with 1% (by volume) sodium hypochlorite solution before recording high-resolution lattice images to remove extraneous Agar from the culture medium, the presence of which greatly reduced image resolution. On completion of the microscopic studies of strain MV-2, the sample grid was negatively stained with 4% methylamine tungstate solution. High-resolution TEM (HRTEM) images were recorded at a magnification of ×500000 by using an objective aperture of 80 μm. The lattice fringe spacings measured from micrographs were corrected according to a calibration done on the microscope by using a gold foil at a magnification of ×500000 and a voltage of 200 kV. The fringe spacings were indexed by comparison with published data for magnetite: space group Fd3m, with lattice parameter a = 0.8394 nm.

3. RESULTS

(a) Strain MV-2

Individual bacteria were elongated in morphology and contained a single chain of intracellular anisometric magnetosomes which were aligned along the long axis of the cell (figure 1). The chains comprised rectangular magnetite crystals oriented with their principal axes parallel to the chain direction. Many cells consisted of incomplete chains in which there were regions devoid of crystals, resulting in gaps within the magnetosome chain. However, the structural alignment of crystals separated by these discontinuities remained consistent, suggesting that all the crystals were spatially constrained within a contiguous cellular
matrix. Immature crystals were observed at different positions along the chain and not specifically at the ends of the assembly, as has been commonly observed in the cells of the coccoid bacterium strain MC-1 (Meldrum et al. 1993). Twinned crystals, in which the twin boundary comprised a central plane running perpendicular to the crystal long axis, were occasionally observed (figure 1c).

There was a marked variation in crystal size between different bacteria and along individual chains (tables 1 and 2, figure 2). The graph of length against width (figure 2c) demonstrates that there is considerable variation in aspect ratio for crystals of given length, suggesting that the rates of crystallization of individual particles in sulphide-grown MV-2 cells may fluctuate significantly.

Lattice images of individual crystals showed combinations of \{111\}, \{220\}, \{200\} and \{311\} magnetite fringes. A high-resolution image of a typical magnetosome produced by MV-2 cells is shown in figure 3. The lattice fringes are continuous throughout the particle suggesting that the magnetosome is a well-defined single crystal. Crystals imaged along the \langle 110 \rangle direction showed two sets of \{111\} fringes and a set of \{200\} fringes (figure 3b). The orientation of these

truncated faces were not expressed, suggesting that these faces are stabilized at relatively late stages of crystal growth.

(b) Strain MV-4

Low-magnification images of strain MV-4 showed curved ‘butter-bean’-shaped cells that contained a single chain of intracellular magnetite crystals aligned along the long axis of the bacterium (figure 5a). A significant number of bacteria contained chains of crystals that were disrupted from linearity, possibly because of artefacts associated with sample preparation. However, the effect was more pronounced than for MV-2 cells and suggests that the location of the magnetosome chain in strain MV-4 may not be as rigidly defined within the bacterium as in strain MV-2.

A detailed analysis of the MV-4 magnetosomes showed that the size and shape of the crystals were significantly different from those produced by strain MV-2 (tables 1 and 2, figure 2). In general, the crystals were slightly longer and considerably wider than those formed by MV-2 cells, with an aspect ratio (1.2) comparable with that determined for magnetite crystals synthesized by the coccoid bacterial strain, MC-1 (Meldrum et al. 1993). Many crystals possessed either a cubo-octahedral morphology (figure 4b) characteristic of *Aquaspirillum* (*Magnetospirillum* (Schleifer et al. 1991)) magnetotacticum (Mann et al. 1984a), or a partly elongated cubo-octahedral form, similar to the highly elongated ‘bullet-shaped’ crystals of an uncultured ovoid-shaped magnetotactic bacterium (figure 4c) (Mann et al. 1987a, b). A significant number of MV-4 magnetosomes exhibited irregular morphologies, and were frequently twinned. Twin planes were usually perpendicular to the axis of elongation of the crystals, although a few crystals with a twin plane parallel to the long axis were also observed.

High-resolution electron micrographs confirmed the well-defined single crystal nature of the magnetosomes produced by strain MV-4 (figure 6). Crystals were principally imaged lying in the <110> zone, although a small number were also observed along the <211> and <111> directions. Those viewed along the <110> axis showed multiple sets of lattice fringes (figure 6) which confirmed a cubo-octahedral morphology consisting of {111} and {100} faces. The {111} faces were particularly well defined, and one set of these faces was often aligned perpendicular to the direction of the magnetosome chain. Although most crystals were partly elongated along the <211> direction, several also showed an isotropic cubo-octahedral projection (figure 6).

4. DISCUSSION

The distinct contrast in crystal size and morphology exhibited by magnetosomes formed within the vibrioid bacterial strains MV-2 and MV-4 suggests that there may be different processes of magnetite biomineralization in these organisms. The magnetite crystals of strain MV-2 are virtually identical in morphology to those produced by a previously studied strain, MV-1 (Sparks et al. 1990). The mean crystal dimensions are very similar for both bacteria, although the dimensional range is considerably greater for MV-1. The number of crystals is greater and the crystal anisotropy more evident in the MV-2 strain, although both bacterial strains display aspect ratios which are greater than those reported for coccoid bacteria (Mann et al. 1984b; Meldrum et al. 1993). The differences between strains MV-1 and MV-2 may result from differences in the developmental status of the two cultures. Alternatively, the use of a sulphide-oxygen gradient medium for MV-2 cells, rather than the anaerobic heterotrophic growth medium used in previous studies of strain MV-1 (Sparks et al. 1990), may be responsible for the increased number of magnetosomes observed in MV-2 cultures.

In contrast, the magnetosomes produced by strain MV-4 possess a cubo-octahedral morphology which, in its undistorted form, is similar to the crystal morphology produced by *A. magnetotacticum* cells (Mann et al. 1984a). The elongated variant of this basic form is similar to the bullet-shaped crystals produced by an unidentified, uncultured ovoid-shaped bacterium (Mann et al. 1987a, b). In both cases, the crystals are
elongated along a \( <211> \) axis but the MV-4 crystals are considerably less extended and maintain their centre of symmetry. The bullet-shaped crystals, by comparison, deviate considerably from their idealized morphology and frequently display a kink or curvature in their growth morphology. They also exhibit very different dimensions to the crystals of strain MV-4, having mean lengths and widths of 97.8 nm and 36.9 nm, respectively, and aspect ratios in the range 3.33-4.0 (Mann et al. 1987a). Thus, although the pattern of truncations present on the magnetosomes in strain MV-4 is very similar to that of the crystals in the uncultured ovoid-shaped cells, the bulk morphology of the crystals produced by the former is significantly different.

In summary, it has been demonstrated that the size and morphology of magnetite crystals produced by two cultured strains of vibrioid magnetotactic bacteria are significantly different. Although the biomineralization of magnetite is highly controlled in both strains, the distinct differences in crystal chemistry suggest that there may be a variety of mechanisms involved in the regulation of these functionally important bioinorganic products. It is noteworthy that cells of the vibrioid strain, MV-2, and those of the cocoid strain, MC-1 (Meldrum et al. 1993) produce magnetosome particles of magnetite, rather than an iron sulphide such as greigite (FeS\(_2\)), in the presence of hydrogen sulphide. Iron sulphides including greigite (Heywood et al. 1990) and pyrite (FeS\(_2\)) (Mann et al. 1990) are found in the magnetosomes of some other magnetotactic bacteria which grow in the presence of hydrogen sulphide. Thus, the composition of the mineral phase of the magnetosomes appears to be controlled by the organism. The factors involved in the species- or strain-specific control of the composition, morphology and particle size of the mineral phase of the bacterial magnetosomes remain to be elucidated, and will be addressed in future work.
