Acknowledgements

I would like to give my thanks to my friend, Kevin Ersoy, who helped developed the idea for this project. Also my friends and colleagues who helped me with any problems and difficulties I had along the way, especially Manny Tarog. Finally, I would like to thank my advisor, Professor Chris Lupo, for the guidance he has given during the period of work for this project.
**Introduction**

Energy is being used in every household without the owner’s knowing. Many major appliances are designed with user convenience in mind by creating a standby mode. The main purpose of a standby mode is to allow the electrical appliance to receive a signal from an external source. For example, a television will have standby mode to receive a signal from a remote control. The same idea goes for similar systems such as a DVD player and stereo receiver. Another reason for standby mode is to retain the user customized settings such as picture settings of a television. This kind of energy is sometimes referred to as “vampire energy” and can mean significant amounts of wasted energy. Not only does this waste money for many household owners, but it also accounts for 1% of CO2 emissions (Meier).

To prevent wasted energy caused by standby mode, it is obvious that users of the device should simply turn off the device from the wall when it is not in use. However, this could be difficult with a significant amount of family members, especially having younger kids in the house that might not be as responsible with all the gadgets they use today. Another way of saving power is to purchase appliances with low power consumptions ratings, which is usually about 1 watt (“Home Energy Usage Tips #1 – Standby Power”).

To give an idea of how standby power affects the world, here are some interesting facts provided by the Student Sustainability Education Coordinators at Berkeley:

- 6% of the entire residential electricity consumption is from standby power.
- California would not experience rolling blackouts if “vampire energy” were eliminated.
• Americans consume 26% of the world’s energy despite being 5% of the world’s population.

It would be ideal if the user were able to control the power usage of these common electronic devices. Although there are government compliances for companies to follow, this project will explore a different approach and allow household owners to monitor and control their energy usage. This report explains a simple simulation of this system and explores a theoretical view of how this system can be used in a household.
System Requirements

The user will be welcomed to the system by a start screen, which will include the current time and instructions to press enter to activate the menu. There will be a series of submenus for the user to perform desired tasks such as controlling power outlets, setting up the automation system for certain devices at user defined on and off times, and viewing current power consumption. Since this is a simulation of turning off power outlets in a household, we will have two rooms to control two devices in each room. The user should be able to control this system by keyboard and the system should respond accordingly. To visually show the user that devices are being turned on/off, four LEDs will be used to represent each device.
System Specifications

User Interface

The user is presented with a menu on the LCD component of the Nexys board. The user is presented with a start screen, which shows the current time of day and instructs them to press enter to continue system operation. The menu should allow them to control power of two rooms, each with two components, setup an automation system to turn off/on devices at user inputted designs, and display the current power being used by each room and each component. To visually display each device, an LED will be used to show if the device is on or off.

Keyboard

A keyboard will be used for the user to interact with the menu and is very simple. This includes navigation by the up/down arrows, selecting submenus by numbers, setting up the automation system, and turning on/off devices. Incorrect input should be ignored. For example, if the user selects a submenu that does not exist, then the system will ignore the input and do nothing.

Automation System

The automation system should give the ability to set up on and off times for the devices. The user will input in a “12:00:00 am (or pm)” format. The seconds should not be specified since most timing devices do not request it from the user. If an invalid time is inputted, the user will be presented with a “Time invalid” message and the on and off times will not be saved for the device. At this point, the user must redo this operation for
their desired on and off times. When the on time of a device occurs, the representative LED of the device will switch on. Likewise, when the off time of a device occurs, the representative LED of the device will switch off. If the device is already on, and the on time occurs, the device remains on. This same operation happens if the off time occurs when the device is already off.

**Controlling Power**

The user should be able to turn on and off each device. Each room should indicate the power being used when they are presently in that submenu. If the user selects a room, each device should indicate the power being used. At this point the user can select which device to turn on/off by selecting ‘ON (Y)’ or ‘OFF (N)’ via keyboard input. The appropriate LED should be turned on/off.

**Digital Clock**

The digital clock is displayed on the start screen. The automation system utilizes the digital clock to compare on/off times of devices after each minute.
System Architecture

The hardware includes the MicroBlaze soft-core processor and all the bus routing. The BRAM (Block RAM) is where all the instructions are stored and accessed. The ILMB (instruction local memory bus) and the DLMB (data local memory bus) control the accessing of data and instructions located in the BRAM. The GPIO (general-purpose I/O) modules are used in conjunction with the OPB (on chip peripheral bus) to control the peripheral devices. The following components utilize GPIOs to operate:

- LCD Control and Data
- Nexys on-board LEDs
- Device loads
- Analog Multiplexer control bits

Figure 1 System Architecture
The timer/counter is another main component of the system. The timer/counter requires a clock input and will generate an interrupt output. The timer/counter output is connected to the MicroBlaze interrupt and should generate an interrupt every second. To communicate with the keyboard, the UART Lite IP core will be used to transfer data from the PS/2 component to the Nexys board. Similarly, an SPI IP core will be used to communicate with the Digilent PmodAD1 to obtain digital signals of voltage readings.

Figure 2 Load Schematic
Component Design

Hardware

Nexys Development Board

The Nexys development board’s Spartan 3-200 microcontroller will be used as the primary hardware component of the system. The LCD screen will be connected to the 16-pin header (J8 port) on the Nexys board. The on-board LEDs will be used for testing purposes, more specifically, confirming software design and correct device selection. The 6-pin headers (JA-JD) will all be utilized in this design. The keyboard will be used for user input and will be connected to the JA header via PS/2 connector. The JB header will support voltages being supplied to the load circuitry, turning on/off LEDs to represent devices. To show power consumption readings by each load, an analog multiplexer will be used to select which loads to measure by control bits out of the JC header. The readings of each load will be received by the Digilent PmodAD1, which is connected to the JD header.

Figure 3 Nexys Development Board
**LCD Screen**

The user interface comprises of the LCD and a keyboard. The LCD interfaces with the Nexys board by using two general-purpose I/Os (GPIO). The LCD requires one GPIO for transmitting commands to the LCD such as clearing the screen, moving the cursor, delays, etc. The other GPIO is used for transmitting data to be displayed on the LCD screen.

**Keyboard**

The main interaction with the system is through the keyboard. The PS/2 connector is used to connect the keyboard to the Nexys board. The UART Lite IP core is used to communicate between the PS/2 connector and the Nexys board so input. The UART Lite stands for Universal Asynchronous Receiver/Transmitter and is used to transfer bits from a receive FIFO or to a transmit FIFO. The UART Lite transfers 5-8 data bits per transfer. Considering scan code for keys are 8 bits in length, the UART Lite served as the perfect IP core for communication with the keyboard.

![Figure 4 User Interface of System](image-url)
Device Loads

The LEDs are the “loads” of the system to create a visual representation of devices of the system. This was implemented using a GPIO with a 2-bit data bus width, one bit for each load. The loads are connected to the JB 6-pin header of the Nexys board where two data pins are used for the two loads as well as the ground pin.

![System Setup with One Load Integration](image)

**Figure 5** System Setup with One Load Integration

16-Channel Analog Multiplexer

A 16-Channel Analog Multiplexer is used to receive the two current sensor output voltages and outputs the selected channel via control bits. Proper operation requires 5V. Although this is a 16-channel analog multiplexer, only two channels are used for the two loads.

![CD74HC4067 Analog Multiplexer](image)

**Figure 6** CD74HC4067 Analog Multiplexer
Current Sensors

The Hall effect based ACS712 current sensors are used for determining current going through the load and requires $5\, V_{CC}$. The sensor outputs an analog voltage that varies linearly with the current. Each load has a current sensor and outputs the voltage to an analog multiplexer. Since we are interested in power consumption, the voltages are translated into current measurements.

![ACS712 Current Sensor](image)

**Figure 7** ACS712 Current Sensor

![Output Voltage versus Sensed Current](image)

**Figure 8** Linear Relationship Between $I_{P}$ and $V_{OUT}$
Analog Mux Control Bits

Similar to the loads, the multiplexer control bits are implemented using a GPIO IP core. However, only a 2-bit data bus width is required. The bits are used as data selectors to read voltages of each load.

Analog-Digital Converter

The signal is transmitted to the PmodAD1 analog-digital converter to be used by the software. To communicate with the Nexys board, a Serial Peripheral Interface (SPI) IP core is used to for fast data transfer from the analog-digital converter.

Figure 9 PmodAD1 Analog to Digital Converter

Software

Timer/Counter

The 32-bit timer/counter was initialized in order to generate an interrupt every half second for the digital clock function. With the microprocessor running at 50MHz and requiring an interrupt every half second, it is determined that the load register of the timer/counter should be loaded with half the processing speed (25,000,000). The counter is set to count down from the load register value. The compiler needs to determine what function to jump to when an interrupt occurs. The syntax that designates the interrupt service routine (ISR) is `my_isr()`__attribute__((interrupt_handler)). When the load register value is zero, the ISR first checks the interrupt bit of the timer/counter’s
status register to check if an interrupt has occurred. The ISR then runs and at the end, the interrupt bit is cleared in order for another interrupt to occur.

*Digital Clock*

When an interrupt occurs, the proper action is to call the function `void update_time()` to handle updating the time display when an interrupt occurs every other half second. Manually updating the time is a separate function called `void manual_update()`. The firmware determines if the proper buttons have been pushed in order to see if control should be handed off to this function. If not, then the clock will operate normally.
Figure 10 Flow of Operation of Digital Clock

**LCD Software**

The LCD software is comprised of initialization and common LCD functions such as clearing the screen and shifting the cursor. Correct initialization of the LCD ensures that characters are displayed correctly. To initialize the LCD, a 20mS delay is required after power on before sending a function set command. The function set determines the data length, number of lines, and display font. After this command, a 37uS delay is needed before turning the display on. The next command is clearing the display after waiting
another 37uS. Finally, a 1.52mS delay is required before going into entry mode. From here, we can now write characters to the LCD. A delay is required before writing each character.

![Flow of Operation of LCD](image)

**Figure 11** Flow of Operation of LCD

*Keyboard Software*

The keyboard is the main component for user the to interact with the system. The software is quite simple for the keyboard. The keyboard uses the UART Lite to communicate with the Nexys board. First, the software checks if there is valid data received in the receive FIFO. If so, the data receive register is checked and the data is held there until it is used to take care of debouncing. Finally, the scan code for the key
pressed is then saved in a variable for use. To translate the scan code into a character, a look up table is used.

**Menu Navigation**

Navigating through the menu is done by user input. The program should continuously wait for the user to provide a valid keystroke to navigate through the menu. At power on, the start screen consists of the digital clock and instructing the user to press enter to continue. They are then presented with the main menu with three options: Control Power, Setup, and Information. The Control Power submenu allows the user to select which room to view, Room 1 or Room 2. In each room, there are 2 devices the user is can switch on/off. The Setup submenu brings the user to the automation system where the user can designate on and off times of a device in one of the rooms. If the user selects Information, the user will be informed of the current total power consumption of the devices.

**Automation System**

The user is allowed to set on and off times for devices. When the automation system is accessed, the user selects the room the device is located in followed by the desired device to set times for. Afterwards, the user will enter a turn off time, followed by a turn on time. There is no need for the user to worry about entering ‘:’ characters for the time since they will automatically be inserted. Also, on and off times are limited by the hour and the minute values as well as the am/pm characters. Therefore seconds will always be ‘:00’. After both times are entered, the next step is testing if the times entered are valid. If one of the entered times is not valid, then the time will not be saved for the selected
device and the user must re-enter valid times. As the digital clock is running, on and off
times of each device is checked at after every minute and the correct devices should be
turned on/off according to device on and off times.

![Figure 12 Flow of Operation for Menu Navigation](image)

**Switch Components**

When the user navigates through the menu and is presented with the choice to turn on/off
a device, a global variable ‘device’ is updated with the ID number of the device selected.
This global variable is then passed into the function `switchComp(int device, int onOff)`
where ‘device’ is the load to switch off and ‘onOff’ determines whether the user
requested the device to turn on (onOff = 1) or off (onOff = 0). When a device is requested
to be turned on, the device ID, which is a hexadecimal number, is ORed with a global
variable ‘leds’ to turn on the load.

```c
leds |= device;
```
Turning a device off involves more complicated bitwise operations. First, we must ensure that the device is not turned off already. If it is not, then we can update the global variable ‘leds.’ To do so, we take flip the bits of the device ID and XOR it with ‘leds’.

\[
\text{leds} = (\text{leds} \oplus \sim \text{device});
\]

After the appropriate bitwise operation, the LCD screen will display a confirmation message of what device was turned on or off. Finally, the user will be taken back to the beginning of the menu.

*Power Measurements*

The power measurements are given in kWh/day. It will appear when the user selects a device to turn on/off through the Control Power menu. When the device is selected, mux control bits are sent to the analog multiplexer to select which device to read from. The analog multiplexer then sends a signal to the analog-digital converter. The digital value will be in a range 0 to 4095 behaving linearly with 0.0V to 3.3V. The digital signal received must be compared with the output voltage of the current sensor referencing 0.0A, which is 2.5V. Converting the 2.5V by a simple calculation indicates that the digital signal value for 2.5V is roughly 3103. This value will be used to scale up the output voltage since the load circuit is being supplied 5.0V. After confirming the rate of voltage change in relation to current of the current sensor, the value scaled can then be converted into amperage. From this point, we can calculate power in watts using the following equation:

\[
P = IV
\]
The voltage (V) in this equation is the supply voltage 5.0V. Now the power will can be converted into kWh/day. To do so, the wattage is divided by 1000 to obtain kilowatts and then multiplied by 24 hours.
Testing

After a component was integrated, it was necessary to test that each component was operating properly by running simple operational tests.

The first component that was integrated was the LCD screen. After setting up the appropriate memory space and GPIO for the component, “Hello World” was sent to the screen. Next, the keyboard and PS/2 connector was implemented to communicate with the UART Lite. Before we can see proper output of the keyboard, it is necessary to obtain the correct baud rate of the keyboard for communication. Baud rates are not a specification that is readily known or listed by keyboard manufacturers. In the case of this project, the baud rate had to be measured with an oscilloscope. Using the oscilloscope, a key is depressed and the waveform is captured. The frequency of the waveform is measured and indicates the baud rate of the keyboard. Since the baud rate of most of the keyboards is not matched to the 9600 or 19200 of the UART parameters, the following equation is used:

\[ \text{OPB Clk Freq.} = (50\text{MHz} \times \frac{9600}{\text{Measured Baud Rate}}) \]

Another important component to test was the output of supply voltages to the load circuits. Since any device can be turned on while other devices are already on and vice versa with devices being off, bitwise operations were required to do this. Before supplying 3.3V to the selected pins of the 6-pin header, correct device selection was tested by outputting to the on-board LEDs. After confirming proper bitwise operation by visual inspection, the output was then routed to the 6-pin header (JB port). Device selection was then tested again by confirming 3.3V(on) or 0.0V(off) output after selecting
what device to turn on/off and measuring the appropriate pin via a multimeter. The same procedure was done for the control bits of the analog multiplexer.

As with components, all software additions were tested incrementally to ensure proper navigation, operation, and execution for a desired result. On-board LEDs were used first to test when selected devices were switched on and off. The automation system required significant testing since this allowed the user to input on/off times rather than selecting menu options. First, it was confirmed that the user input matched the output on the screen. After entering on and off times, the software confirms if the times entered are valid. Otherwise, times are not saved and the user must re-enter valid on and off times. After confirming both operated correctly, on and off times of one device was tested. The digital clock on the start screen was observed until the on and off times occurred. Output was rerouted to an on-board LED and turned on and off at the set times. Afterwards, the automation system was scaled up to support all four loads and outputs were rerouted back to the supporting load circuits.

The main concern for building an appropriate circuit for the load was having a significant amount of current for the current sensor to detect. A voltage reading of the current sensor of 0.18V is translated into 1A. This measurement is on a much larger scale than what the original design anticipated. Therefore, a circuit was designed to draw a current of approximately 0.5A. In order to do this, resistor values power ratings had to be heavily considered in order for them to operate within their range and still generate a 0.5A current. It was determined that a number of resistors should be put in parallel in order to reduce the amount of current running through each. When the circuit was implemented successfully running at approximately 0.5A with a power supply, the
current sensor was then measured and a significant reading of 2.57V was outputted. This corresponds with 0.5A running through the circuit.

Another significant component to test was the analog-digital converter (ADC) that will receive select signals from the analog multiplexer. After setting up the SPI to interface with the ADC, a test analog signal was sent from a power supply to the ADC. An analog signal that would be approximate to a value produced by the system was chosen. Therefore, we chose 2.57V, which is the output voltage of the current sensor of the test circuit. Manual calculations of power in kWh/day were done to confirm the correct output value on the LCD. The value appeared to be off by ~10%. This could be due to the rounding during manual calculations or inaccuracy of a power supply that is not calibrated to industry standards.
Roadblocks and Problems / Solutions

The original design allowed the user to add rooms and devices to the system. However, with the needed peripherals and the limited ports of the Nexys board, only one 6-pin header could be used resulting in the system supporting four loads. To power the loads, the IME156 power supply box was used. This provided an easy and available power supply to have at home. However, the accuracy of the power supply output voltage is inexact. To ensure that the correct voltage was being supplied to the supporting loads of the system, the voltage was periodically measured via a portable multimeter.

Another problem encountered was obtaining the correct baud rate for the keyboard to work properly. The first keyboard that was used would display unknown characters when keystrokes occurred. This led to the belief that the UART was functioning correctly but the baud rate was inaccurate. It was found that it is very important to measure the frequency of the keyboard waveform at the smallest transition between a high and a low. Failure to do this will lead to an incorrect baud rate measurement that will result in faulty keyboard operation.

A big challenge of this project was the implementation of the current sensor. The ACS712 current sensor was designed to sense current at a much higher range. As mentioned before, an output of 0.25V translates into 1.0A of current, which is much more than the original design anticipated. Therefore, current could not be sensed since the current being drawn was in the range of 20-25mA. According to this measurement, the voltage output would be a constant ~2.5V, which indicates almost no current or in this case, a very small amount. To obtain a significant reading, a circuit was designed to draw 0.5A.
One of the main problems of the system when implemented with the Nexys board is the voltage drop of the I/O pin supporting the loads. This is due to supporting the load of the system. The I/O pins of the headers of the Nexys board are capable of supporting 100mA of current. Since the load has a significant amount of current going through it, the Nexys board must compensate by dropping the input voltage of 3.3V. This alters the current of the load significantly from 0.5A to about 0.19A. Since this was the case, the LED of the load no longer indicated that the load was on. Therefore the circuit was modified by removing some of the resistances in parallel to provide more current to the LED. Before, when testing the system with 0.5A, the power supply was able to supply more than 100mA of current and therefore was a more ideal power supply versus the Nexys board.

Although the current of the loads have dropped significantly, the current sensor is still able to read the current going through the load. When tested with the power supply to generate 0.5A, the output of the current sensor was 2.57V. When implemented with the Nexys board, the current sensor now generates 2.53V. This is still a readable signal to convert to kWh. However, the signal of the analog multiplexer is slightly noisy on the millivolt scale. This is relatively on the small scale but allows for significant fluctuation of the kilowatt-hours being calculated by several tenths. For example, if the voltage reading of the current sensor of a load ranges from 2.531V to 2.536V, then the kilowatt-hours will range from 1.28kWh to 1.49kWh, which is a significant change.
Results

After testing and determining necessary modifications, the system was able to determine the power used by the loads. The system as a whole proved to be functional for a user to turn on and off loads from a simple to use interface. First, the LCD was successfully implemented to display the menu. Next, the correct baud rate was obtained to successfully connect the keyboard to the system for the user to navigate through the menu and execute operations such as turning on and off loads. After a menu was setup, loads were connected via GPIOs after outputting to LEDs to verify correct bitwise operations. Once successfully implemented, the automation system was applied to the system to turn on and off loads at user-inputted times. Loads were then constructed for carrying 0.5A in order to obtain a significant current sensor reading. However, after connecting it to the Nexys board, it was seen that this was not possible considering the current that the Nexys I/O pins could supply only 100mA. This lowered the supply voltage from the Nexys board, which also lowered the current going through the load. Fortunately, this was readable by the current sensor and was able to be converted to a kWh value and outputted to the LCD.
**Future Work and Impact In Today’s World**

A web application or a computer program could be implemented via Bluetooth to report more comprehensive data such as power consumption throughout the day in graphical form. The website would provide the same information the user is able to view on the LCD display. Graphical representation of power usage throughout the day would give the user more awareness of the peak power consumption times. The user should be more inclined to save power and money after viewing such information. Also, the website will inform the user of each device and their power usage as well.

A redesign could be applied to actual AC outlets and could be tested with actual devices to replace simulation purposes. However, the Nexys Development board will be unable to provide enough current to the supporting circuitry considering the roadblocks mentioned. This redesign would call for a high power system to handle the actual loads of the household devices.

Such a system as this could help household owners lower electricity bills and improve energy consumption considering the heavy concern of energy efficiency and becoming a greener planet by reducing CO₂ emissions. The idea of this system is to help household owners become more aware of their power consumption due to “vampire energy” of devices in idle state and encourage them to lower the energy used by idle devices in their own home. Also, the system allows the user to easily monitor outlets and control them from one unit without physically unplugging devices.

In a recent study by Lawrence Berkeley National Laboratory, the standby power was measured for common household devices. A number of measurements were taken
over a variety of the same kind of type of device. The average standby power was then calculated for that particular device. To gain a sense of the potential savings, we will observe the highest average recorded: 36.5 Watts standby power for a set-top box DVR. This results in 0.0365 kilowatts. Having this type of device in standby mode, we have potential savings of $0.08/day, $2.36/month, and $28.38/year.
Conclusion

Overall, the project was a success as it simulated devices being switched on and off from one unit. This project dealt heavily with digital design and microprocessor based programmable logic as well as fundamentals of electrical engineering. Despite the setbacks, which were explained in “Roadblocks and Problems / Solutions,” the purpose of this project was to propose a household product idea in order for people to be more aware of their energy use. In the end, this was successfully accomplished, as the user was able to turn off different “outlets” or loads, view power consumption, and setup an automated system to help them save energy and money.

This project required design of both hardware and software, strong aspects of computer engineering. The software side required a good amount of interfacing between the Nexys and its peripherals and components such as the UART for translating keystrokes from the keyboard connected via PS/2 connector, and the SPI with the PmodAD1 in order to calculate DC power measurements for each load. With many components involved, it was very important to test each aspect of the project as they were implemented on to the system. This helped isolate problems when they arose.

A great deal of work was put into this project, from research to implementation. It required a vast amount of patience and thinking outside the box if problems hindered progressing forward. Also, completing a project individually cannot be done, as there were many times that assistance was asked from students or professors better skilled in a certain part of the project where their expertise became useful.

Appendix G: Analysis of Project

This appendix includes applicable information in response to the “Analysis of Senior Project Design” questions.

Summary of Functional Requirements
Describe the overall capabilities of functions of your project or design. Describe what your project does. (Do not describe how you designed it.)

The user will be welcomed to the system by a start screen, which will include the current time and instructions to press enter to activate the menu. There will be a series of submenus for the user to perform desired tasks such as controlling power outlets, setting up the automation system for certain devices at user defined on and off times, and viewing current power consumption. Since this is a simulation of turning off power outlets in a household, we will have two rooms to control two devices in each room. The user should be able to control this system by keyboard and the system should respond accordingly. To visually show the user that devices are being turned on/off, four LEDs will be used to represent each device.

Primary Constraints
Describe significant challenges or difficulties associated with your project or implementation. For example, what were limiting factors or other issues that impacted your approach? What made your project difficult? What parameters or specifications limited your options or directed your approach?

The original design allowed the user to add rooms and devices to the system. However, with the needed peripherals and the limited ports of the Nexys board, only one 6-pin header could be used resulting in the system supporting four loads. To power the loads, the IME156 power supply box was used. This provided an easy and available power supply to have at home. However, the accuracy of the power supply output voltage is inexact. To ensure that the correct voltage was being supplied to the supporting loads of the system, the voltage was periodically measured via a portable multimeter.

Another problem encountered was obtaining the correct baud rate for the keyboard to work properly. The first keyboard that was used would display unknown characters when keystrokes occurred. This led to the belief that the UART was functioning correctly but the baud rate was inaccurate. It was found that it is very important to measure the frequency of the keyboard waveform at the smallest transition between a high and a low. Failure to do this will lead to an incorrect baud rate measurement that will result in faulty keyboard operation.
A big challenge of this project was the implementation of the current sensor. The ACS712 current sensor was designed to sense current at a much higher range. As mentioned before, an output of 0.25V translates into 1.0A of current, which is much more than the original design anticipated. Therefore, current could not be sensed since the current being drawn was in the range of 20-25mA. According to this measurement, the voltage output would be a constant ~2.5V, which indicates almost no current or in this case, a very small amount. To obtain a significant reading, a circuit was designed to draw 0.5A.

One of the main problems of the system when implemented with the Nexys board is the voltage drop of the I/O pin supporting the loads. This is due to supporting the load of the system. The I/O pins of the headers of the Nexys board are capable of supporting 100mA of current. Since the load has a significant amount of current going through it, the Nexys board must compensate by dropping the input voltage of 3.3V. This alters the current of the load significantly from 0.5A to about 0.19A. Since this was the case, the LED of the load no longer indicated that the load was on. Therefore the circuit was modified by removing some of the resistances in parallel to provide more current to the LED. Before, when testing the system with 0.5A, the power supply was able to supply more than 100mA of current and therefore was a more ideal power supply versus the Nexys board.

Although the current of the loads have dropped significantly, the current sensor is still able to read the current going through the load. When tested with the power supply to generate 0.5A, the output of the current sensor was 2.57V. When implemented with the Nexys board, the current sensor now generates 2.53V. This is still a readable signal to convert to kWh. However, the signal of the analog multiplexer is slightly noisy on the millivolt scale. This is relatively on the small scale but allows for significant fluctuation of the kilowatt-hours being calculated by several tenths. For example, if the voltage reading of the current sensor of a load ranges from 2.531V to 2.536V, then the kilowatt-hours will range from 1.28kWh to 1.49kWh, which is a significant change.

Environmental
Describe any environmental impact associated with manufacturing or use.

Such a system as this could help household owners lower electricity bills and improve energy consumption considering the heavy concern of energy efficiency and becoming a greener planet by reducing CO\textsubscript{2} emissions. The idea of this system is to help household owners become more aware of their power consumption due to “vampire energy” of devices in idle state and encourage them to lower the energy used by idle devices in their own home. Also, the system allows the user to easily monitor outlets and control them from one unit without physically unplugging devices.

In a recent study by Lawrence Berkeley National Laboratory, the standby power was measured for common household devices. A number of measurements were taken over a variety of the same kind of type of device. The average standby power was then calculated for that particular device. To gain a sense of the potential savings, we will observe the highest average recorded: 36.5 Watts standby power for a set-top box DVR. This results in 0.0365 kilowatts. Having this type of device in standby mode, we have potential savings of $0.08/day, $2.36/month, and $28.38/year.

Sustainability
Describe how the project impacts the sustainable use of resources.

One of the project’s main purposes is to make the user more aware of the energy their household is consuming, more specifically standby power. Standby power accounts for 1% of CO\textsubscript{2} emissions, which is detrimental to the environment. The use of this project would help reduce energy usage and CO\textsubscript{2} emissions.

Describe any upgrades that would improve the design of the project.

The design could be applied to actual AC outlets and could be tested with actual devices to replace simulation purposes. A web application or a computer program could be implemented via Bluetooth to report more comprehensive data such as power consumption throughout the day in graphical form. The website would provide the same information the user is able to view on the LCD display. Graphical representation of power usage throughout the day would give the user more awareness of the peak power consumption times. The user should be more inclined to save power and money after viewing such information. Also, the website will inform the user of each device and their power usage as well.
o Describe any issues or challenges associated with upgrading the design.

With the upgrades mentioned above, the Nexys Development board will be unable to provide enough current to the supporting circuitry considering the roadblocks mentioned above. This redesign would call for a high power system to handle the actual loads of the household devices.
