Multiple Evolutionary Origins of Magnetotaxis in Bacteria

Edward F. DeLong,* Richard B. Frankel, Dennis A. Bazylinski*†

Magnetosomes are intracellular, iron-rich, membrane-enclosed magnetic particles that allow magnetotactic bacteria to orient in the earth's geomagnetic field as they swim. The magnetosomes of most magnetotactic bacteria contain iron oxide particles, but some magnetotactic species contain iron sulfide particles instead. Phylogenetic analyses of small subunit ribosomal RNA sequences showed that all known magnetotactic bacteria of the iron oxide type are associated with the α subgroup of the Proteobacteria in the domain Bacteria. In contrast, uncultured magnetotactic bacteria of the iron sulfide type are specifically related to the dissimilatory sulfate-reducing bacteria within the δ subdivision of the Proteobacteria. These findings indicate a polyphyletic origin for magnetotactic bacteria and suggest that magnetotaxis based on iron oxides and iron sulfides evolved independently.

Magnetotaxis in bacteria (1) is the result of a permanent magnetic dipole moment that causes a cell to be oriented in the earth's geomagnetic field as it swims (2). The magnetic dipole moment is caused by the presence of magnetosomes (3), intracellular, iron-rich, membrane-enclosed magnetic particles. In most magnetotactic bacteria, the particles consist of the ferrimagnetic iron oxide magnetite (Fe₃O₄) (4–8). However, some magnetotactic bacteria collected from sulfidic, brackish-to-marine aquatic habitats have recently been found to contain iron sulfide particles (9, 10), including ferrimagnetic greigite (Fe₃S₄) (9, 11, 12) and nonmagnetic pyrite (FeS₂) (9, 11). Although magnetotactic bacteria of both the iron oxide and iron sulfide types are frequently found in the same habitats, they grow in discrete locations, as indicated
by vertical oxygen and sulfide concentration gradients (13). However, iron sulfide-type magnetotactic bacteria have not been cultivated to date, and their relation to iron oxide-type magnetotactic bacteria has not been described.

Magnetotactic bacteria were collected from sulfidic, brackish-to-marine sediment and water from various coastal sites in New England with the use of a modified mate-track technique (14). A magnetotactic, many-celled prokaryote (MMP) (15, 16) was collected in large numbers, but could not be cultured. Transmission electron microscopy and energy-dispersive x-ray analysis of the magnetosomes in this organism showed that the magnetosomes contained only iron and sulfur, consistent with the presence of greigite and pyrite (9). Three magnetotactic cell types were also isolated and cultured for comparative purposes. These included the first coccal strain to be cultured axenically, designated MC-1 (17), and two vibrioid strains, designated MV-1 (8) and MV-2 (17). Transmission electron microscopy and electron diffraction have determined that strains MC-1 and MV-2 contain particles of magnetite (18).

Nucleic acids were purified from magnetotactic bacteria, and the small subunit ribosomal RNA genes (ssu rRNA) were amplified, cloned, and sequenced (19). Distance-matrix analyses (Fig. 1A) and maximum-parsimony analyses (Fig. 1B) of the ssu rRNA sequences of the cultured, iron oxide-type magnetotactic bacteria indicated that these bacteria were members of the α subdivision of the Proteobacteria (20) in the domain Bacteria. The rRNA sequences of the magnetite-containing vibrioid strains MV-1 and MV-2 were identical and fell within the α subdivision. However, these strains were not closely related to any previously characterized magnetotactic species, including the magnetotactic spirilla Magnetospirillum (formerly Aquaspirillum) magneto-tacticum (21) and M. greiphiwaldense (22) or to several uncultured magnetotactic cocci (23). Unrestricted rRNA sequence similarity values between strain MV-1 and other α Proteobacteria ranged from 0.83 to 0.87. The magnetite-containing cocccus, strain MC-1, was more peripherally related to the α Proteobacteria group. Ribosomal RNA sequence similarities between strain MC-1 and its closest relatives, a group of different, uncultured, freshwater magnetotactic cocci (23) (CS103, CS306, and CS310; Fig. 1), ranged from 0.85 to 0.87. Secondary structural analyses support the inclusion of the magnetite-containing magnetotactic bacteria within the α subdivision of the Proteobacteria. For example, strain MC-1 contained a 3-base pair stem between nucleotide positions 184 to 193 (Escherichia coli numbering) and a shortened helix between nucleotide positions 198 to 219. These combined features distinguish members of the α subdivision from those of the β, γ, and δ subdivisions of the Proteobacteria (24).

Phylogenetic analyses of the ssu rRNA sequence of the MMP indicated the affiliation of this bacterium with the δ subdivision of the Proteobacteria (Fig. 1). This

Fig. 1. Phylogenetic relations of iron oxide- and iron sulfide-type magnetotactic bacteria. Synechococcus PCC 6301 and Planctomyces staleyi are included as outgroups to the Proteobacterial lineage. (A) Evolutionary distances were estimated with the correction of Jukes and Cantor (27) from 630 aligned, moderately to highly conserved nucleotide positions. Phylogenetic tree topology was inferred with the least squares distance-matrix analyses software of Olsen (28) obtained from the ribosomal RNA database project (29). Scale bar represents five fixed mutations per 100-nucleotide sequence positions. (B) Results of maximum-parsimony analysis (PAUP version 3.0s) and bootstrap resampling of the dataset (30–32). The tree topology summarizes the results obtained from 100 trees generated from 100 individual bootstrap resamplings of the dataset. Values indicate the percentage of bootstrap resamplings that yielded the branching pattern to the right of that value in the majority-rule consensus tree. Sequences (33) obtained in this study are in bold type.
The type of magnetosome mineral appears to reflect phylogenetic affiliation. All iron oxide–type magnetotactic bacteria examined in this study and elsewhere (21–23) are specifically affiliated with the α subdivision of the Proteobacteria. In contrast, the iron sulfide–type MMP is affiliated with the dissimilatory sulfate-reducing bacteria in the δ subdivision of the Proteobacteria. The data suggest that iron sulfide–type magnetotactic bacteria (11, 12) other than the MMP are also probably associated with the dissimilatory sulfate-reducing Proteobacteria. Because the subdivisions of the Proteobacteria are comprised of four distinct, coherent phylogenetic lineages that have diverged at an unknown time in the past (24, 26), it appears that magnetotaxis based on iron oxides and iron sulfides has separate evolutionary origins. Moreover, the biochemical basis for biomagnetization and magnetosome formation for iron oxide–type and iron sulfide–type bacteria are likely fundamentally different. The advantage conferred by magnetotaxis is presumably an increased efficiency in finding and maintaining position relative to chemical and redox gradients. It is remarkable that both types of magnetotactic bacteria converged on similar solutions to the problem of magnetotaxis—construction of a permanent magnetic dipole moment sufficient to orient the cell in the geomagnetic field by using different magnetic minerals.

REFERENCES AND NOTES

17. Strains MC-1 and MV-2 were isolated from water collected from the Pettaquamscutt Estuary in Rhode Island.
19. Cells of the MMP were lysed and the nucleic acids extracted as previously described [E. F. DeLong, Proc. Natl. Acad. Sci. U.S.A. 88, 5686 (1991)]. A 1.5-kb region of the ssu rRNA gene was amplified by PCR [R. K. Saki et al., Science 239, 487 (1988)] with the use of oligonucleotides primers broadly specific for the eubacterial rRNA gene [D. J. Lane, in Nucleic Acid Techniques in Bacterial Systematics, E. Stackebrandt and M. Goodfellow, Eds. (Wiley, New York, 1991), pp. 115–175]. Amplified ssu rRNA gene products were cloned into a commercially prepared vector, PCR 1000 (Invitrogen, San Diego, CA), and individual clones were screened by agarose-gel electrophoresis of small-scale plasmid preparations. The cloned rRNA inserts were sequenced by the dideoxy chain termination method with the use of Sequenase 2.0 (U.S. Biochemical, Cleveland, OH), and rRNA-targeted sequencing primers. In some cases, after ammonium acetate precipitation, the double-stranded PCR product was directly sequenced. Amplification of the rRNA genes of the pure cultures was performed as above except that one of the primers was biotinylated. After amplification, the biotinylated strand was purified [T. Hultman, S. Stahl, E. Homes, M. Uhen, Nucleic Acids Res. 17, 4937 (1989)] with the use of avidin-coated magnetic beads (Dynal, Inc., Great Neck, NY) and sequenced directly.
