\textbf{A B S T R A C T}

In practice it is common to estimate site effects using a single proxy, or single variable such as 30 m shear wave velocity ($V_{S30}$) or site period. Many studies have investigated merits of proposed proxies with contradicting recommendations. Yet, most studies indicate the single proxy approach is less than ideal, resulting in large uncertainty. To provide a better understanding of components that drive site response, we performed a parameterized study on 19 shallow soil profiles with $V_S$ ranging from 150 m/s to 400 m/s. We propagated 74 input motions through each soil column using one-dimensional equivalent-linear method to produce 1406 site response analyses. The resulting amplification factors (the ratio of surface to base motion) were then analyzed statistically to identify trends. The mean amplification factor, averaged from 74 records, was used to isolate and quantify the effects of $V_S$ on site response. Based on analysis of record-to-record trends, we identified two separate mechanisms through which nonlinearity affects site response including “damping increase” and “site period shift”. The interaction of these two mechanisms makes amplification-shaking intensity models highly depth-dependent. The residual standard deviation of amplification factor based on depth-independent models was found to be up to three times larger than the corresponding standard deviation based on depth-specific models. We found strain compatible site period a promising site parameter that complements the predictive information obtained from $V_S$. Finally, a simplified procedure providing a five-point estimate of site transfer function is outlined. The proposed procedure can fill the gap in current practice for an intermediate solution between the numerically rigorous solution and the single proxy approach. Implementation of this procedure is demonstrated in an example.

\section{1. Introduction}

Two general approaches are used to estimate site effects on ground motion. A “site-specific” analysis is usually performed for sensitive buildings and large infrastructure like highway or railroad bridges, underground subway stations, lifelines, and dams. The site-specific analysis can be conducted using nonlinear or equivalent-linear methods to propagate shear waves from basement rock to the ground surface. Although three dimensional solutions are available for site response, in most cases a one dimensional (1-D) solution based on assumption of polarized upward/downward shear waves and infinite horizontal layers is practiced. Implementation of site-specific analysis requires resources that may not be readily available for small to medium size projects or in conceptual/bid phase of large projects. Alternatively, generic site factors are used for final design of typical buildings, a wide range of small infrastructure, and in conceptual phase design of large infrastructure. Developing site factors has been done by compiling ground motion data recorded at soil and rock sites during past earthquakes and examining dependence of amplification factor on certain site parameter, also known as site proxy, using multivariable regression techniques (e.g., [1,3,5,6,13,16,26]).

The most commonly used site proxies include descriptive geotechnical or geological classification, shear wave velocity ($V_S$) averaged in top 30 m ($V_{S30}$), or site period ($T_D$). Borcherdt [5] analyzed site response data from 1989 Loma Prieta earthquake and suggested a linear relationship between amplification factor and $V_{S30}$ in natural log scale at short and mid periods for two ranges of peak ground acceleration (PGA) of $< 0.2g$ and $> 0.2g$. Accordingly, a site classification was proposed based on $V_{S30}$ to estimate site factors which were later adopted by the UBC1997 Code [27] and NEHRP Provisions (2009) [17]. Probabilistic seismic hazard analysis (PSHA) practice has gradually evolved to adopt the $V_{S30}$-based approach by incorporating $V_{S30}$ and various depth-related terms, (e.g. depth to $V_S = 1000$ m/s) in ground motion prediction equations (GMPE) including Next Generation of Attenuation (NGA) models (e.g. [2,7,8,12]).

The single proxy approach is simple to use but omits several key
components of site response which leads to large uncertainty of the results. For example, site factors developed from 1989 Loma Prieta earthquake data by Borchert [5] have an standard error of regression of 0.5–0.65 in natural log scale. Choi and Stewart [13] developed amplification factors as a continuous function of $V_{S30}$ and shaking intensity with a regression error ranged from 0.45 to 0.69 in natural log scale. Estimation of amplification factor with an error of such magnitude makes the applicability of the developed transfer functions limited.

There have been numerous studies focusing on merits of various site proxy with contradicting recommendations. Rodriguez et al. [20] used site response data from 1989 Loma Prieta and 1994 Northridge earthquakes to examine the accuracy of various site classification systems. They compared the $V_{S30}$-based classification and a site period-based classification and found the two systems provide similar accuracy in prediction of site response. Stewart et al. [23] used 1828 records from 154 shallow crustal earthquakes and found that a detailed-surface geology classification provides a more accurate prediction of site amplification than either the $V_{S30}$-based or a site period-based classification system for soil sites. Abrahamson [2] favored $V_{S30}$ as a less subjective site parameter to be used in GMPE for deep soil sites common in California and suggested other site parameters can be added to GMPEs. Site period has been found an adequate site parameter by a handful of scholars (e.g. [29,10,19]). Zhao [30] used 3018 KiK-net downhole array record pairs (surface and borehole) from 95 earthquakes in Japan and developed a model for surface/borehole amplification factors. Based on this study, site period was found a better site proxy with lower standard deviation of inter-site residuals of amplification ratios compared to $V_{S30}$ for spectral periods $> 0.6$ s. McVerry [19] analyzed the strong ground motion data that was used in developing New Zealand GMPEs and found site period is a more adequate predictor of site effects than $V_{S30}$, in particular, for deep/stiff sites. Castellaro [9] ran one dimensional equivalent-linear site response simulations for a suite of 585 soil profiles and two simple records including a Ricker wavelet with frequency of 1 Hz and 0.5 Hz and showed a matrix consisting of shear wave velocity of shallower softer layer, site period, and site impedance ratio predicts amplification factor better than $V_{S30}$.

Although a large number of studies suggested the inadequacy of the single proxy approach in general, and $V_{S30}$ as the single site proxy in particular, no consensus has emerged for an alternative approach. The inconclusive research may be attributed to complexity of site response problem which is inherently unresolvable to a single predictor. This paper presents a parametric study of multiple components that are omitted in single proxy approach. The methodology includes performing 1-D site response analysis by propagating 74 ground motions through a suite of hypothetical soil profiles. The resulting suite of amplification factors is analyzed statistically to identify trends. This study attempts to provide some perspective on “which single proxy?” through a better understanding of the contribution of shear wave velocity, site period, and site period shift due to nonlinear soil behavior.

2. Methodology

The general methodology used here is similar to the approach used by [4], [28], and Castellaro [9]. In particular, this study was performed to build upon findings of [4]. The set of soil profiles used in this study covers a broader condition than the set used in [4]. This study includes 19 soil profiles, with $V_s$ ranging from 150 m/s to 400 m/s and the depth to bedrock ranging from 10 m to 75 m. Two soil types, a generic sand and a generic clay (with plasticity index of 40–80) were used. The shear stiffness degradation and damping versus shear strain model [14,21,22,24] for these materials are plotted in Fig. 1. A summary of soil profiles along with the material type, $V_S$, and site periods are presented in the Table 1. Bedrock was assumed to have a $V_S$ of 760 m/s to match the boundary between NEHRP B and C classes.

A total number of 74 records from 27 earthquakes after [4] were run through each soil profile. Most of the ground motions were recorded at rock sites with average $V_S$ of 760 m/s. The recording at the bedrock level is not equal to the recording at a nearby rock outcrop due to reflections and weathering of surficial rock. Following [4], we did not perform deconvolution for two reasons, (1) the main objective of this study is not to provide the best estimate of amplification factor but to investigate parameters and procedures that will lead to better estimate of amplification factor, (2) deconvolution is expected to impact site response at very short period range. Such period range is not usually of interest for infrastructure projects like bridges and tall buildings.

A list of records used in this study and the corresponding spectral accelerations are provided in the electronic supplement. The earthquake magnitudes range from M5.0 to M7.4 with a median value of M6.7, and PGA ranges from 0.01 g to 1.5 g, with median and geometric mean values 0.11 g. The ground motion database used in this study is available at Pacific Earthquake Engineering Research Center website (www.peer.berkeley.edu; accessed November 2010).

We performed equivalent-linear 1-D site response analysis on each soil profile using SHAKE2000 [18]. The appropriate shear strain range for application of equivalent linear method is investigated in several past studies. Bolisetti et al. [11] conclude that the equivalent linear response is inappropriate when shear strain is greater than 1%. Kaklamanous et al. [15] recommended nonlinear method be used for
shear strain greater than 0.4% at short periods, and suggested both equivalent-linear and non-linear methods provide similar results at long period. For the purpose of this study, for each profile, records that induce shear strain values of greater than 0.8% were excluded from our analysis. The number of ground motion records that were excluded ranged from 0 to 8 of the 74 records for different profiles. We also considered setting a lower threshold of 0.5% for shear strain to comply with findings of Kaklamanous et al. [15] This lower threshold would have resulted in exclusion of 0–3 more records from our analysis for some of the softer profiles. We proceeded with a threshold shear strain of 0.8% as it would not affect our key findings.

3. Limitations

We recognize that site response is a complex problem and several contributing components including 3-D effects, topography effects, spatial variability of soil properties and ground motion, incidence angles, primary wave effects, and integrity of bedrock, among others, are excluded from the scope of this study. The idealized conditions of a uniform soil layer over bedrock limits the applicability of our findings. However, this approach reduces the number of contributing components on site response. Such idealization was necessary for tracking the impact of individual components like Vs, site period, and site period shift which could be masked when using more complicated soil profiles based on empirical data. Applicability of our findings is limited to low and medium strain range where use of equivalent-linear method is justified. The impact of nonlinear soil behavior on site response is expected to be more pronounced in very short period range. This period range is of less interest for major infrastructure for which a site-specific site response analysis is sought. Finally, our results do not apply when ground failure including liquefaction, cyclic softening, and excessive seismic deformations take place.

4. Results

It is helpful to define several terms that we use frequently from this point forward. Site period, $T_N^*$, is the period at which soil column would resonate with harmonic loading and can be computed as $T_N^* = \frac{4}{V_s}$, where $H$ is depth to bedrock. Strain compatible shear wave velocity, $V_s^*$, is computed from strain compatible shear stiffness, $G^*$, through $G^* = \rho (V_s^*)^2$ where $\rho$ is density. $G^*$ is a function of shear strain and is determined from the stiffness degradation curve. Strain compatible site period, $T_N^*$, is computed as $T_N^* = \frac{4}{V_s^*}$. The analysis results are first presented for the mean response for each profile averaged from 74 records, followed by the results from individual records.

4.1. Dependence of amplification factor on $V_s$

Amplification factor for 5% damped response spectral acceleration, $A_F$, was computed for each ground motion. We then averaged the amplification factor from the 74 records at any given period, $A_{Fm}$.

Plotted in Fig. 2(a), b, and c are $A_{Fm}$ for generic clay with $V_s$ = 400 m/s, 316 m/s, and 200 m/s, respectively. Similar graphs for generic sand are provided in the electronic supplement. Peak amplification factor (maximum amplification factor across the period range) is denoted by $A_{Fpm}$. Note that $A_{Fpm}$ increases as Vs reduces but remains approximately constant as depth to bedrock increases. Also, note the period at which $A_{Fpm}$ occurs increases as depth to bedrock increases. This period for each soil profile is the strain compatible site period ($T_N^*$). $A_{Fpm}$ is plotted versus $V_s$ in Fig. 3 with each data point representing peak amplification factor averaged from 74 records for one soil profile. We found a strong linear correlation between $A_{Fpm}$ and $V_s$ with coefficients of determination $R^2$ greater than 0.96. $A_{Fpm}$ can be estimated from the following equations where $V_s$ is in m/s:

\begin{align}
\text{Generic Sand} \\ \text{Ln}(A_{Fm}) &= -0.40\text{Ln}(V_s) + 3.07 \\
\text{Generic Clay} \\ \text{Ln}(A_{Fm}) &= -0.54\text{Ln}(V_s) + 3.81 
\end{align}  

Since $A_{Fpm}$ is averaged from 74 records it has minimal representation of “shaking intensity” and “record-to-record” variability. Also, it was shown $A_{Fpm}$ is independent from depth to bedrock. This would make $A_{Fpm}$ a good parameter to use for tracking and quantifying the impact of $V_s$ on site response. Therefore, Eqs. (1) and (2) provide a useful tool to characterize the isolated impact of $V_s$ on amplification factor.

4.2. Amplification factor vs shaking intensity

In this section we investigate the relationship between amplification factor and shaking intensity, also known as nonlinearity model. We examined various shaking intensity parameters, and similar to Bazzurro and Cornell [4], found amplification at any period is best correlated with response spectral acceleration of bedrock at corresponding period, $S_1$. Peak amplification factor across the period range for an individual record, $A_{Fp}$ was found best correlated with spectral
Fig. 2. Amplification transfer functions averaged from 74 records for generic clay (a) $V_S = 400$ m/s, (b) $V_S = 316$ m/s, (c) $V_S = 200$ m/s.

Fig. 3. Peak amplification factors averaged from 74 records versus shear wave velocity.

acceleration of bedrock at site period, $S_a$. Plotted in Fig. 4(a) to (d) are amplification factors at periods of 0.5 s, 1.0 s, and 1.5 s, and peak amplification, $A_F$, versus spectral acceleration of input motion for generic sand with $V_S = 316$ m/s, depth to bedrock of 50 m and site period of 0.63 s ($= 50 \times 50$ m/316 m/s). Each data point shown in Fig. 4 represents an individual record. The following distinct trends for nonlinearity were identified:

- $A_F^S$ shows a strong negative correlation with $S_a$.
- $A_F^T$ first increases with $S_a$ and then drops as $S_a$ increases,
- $A_F^T$ shows a mild positive correlation with $S_a$, and
- $A_F^P$ shows a mild negative correlation with $S_a$.

To explain these trends, two major mechanisms through which nonlinearity operates, should be recognized:

A. Damping increase which de-amplifies the motion as acceleration increases,
B. Stiffness decrease and migration of site period which may amplify or de-amplify the motion due to resonance effects.

For $A_{F_O-S}^S$, the designated period of 0.5 s is smaller than the small strain site period, $T_{N_S}$ of 0.63 s. As $S_a$ increases, strain compatible site period, $T_{N_S}^*$, migrates away from designated period of 0.5 s and resonance effects diminish resulting in amplification reduction. Concurrently, as $S_a$ and shear strain increase, higher damping tends to de-amplify the motion. For $A_{F_O-S}^P$ mechanisms A and B act in parallel leading to strong negative correlation between amplification and $S_a$. For amplification at period of 1.0 s and within the range of approximately $S_a < 0.2$ g, as $S_a$ increases, amplification increases. In this range, strain compatible site period, $T_{N_S}^*$, falls between 0.63 s and 1.0 s; as $S_a$ increases, $T_{N_S}^*$ shifts towards resonance period of 1.0 s which results in amplification increase. In this range mechanism A and B operate in opposite, but, mechanism B controls. For $S_a > 0.2$ g, $T_{N_S}^*$ is greater than resonance period of 1.0. In this range, as $S_a$ increases, site period shifts away from designated period of 1.0 s, combined with increased damping effects, results in sharp reduction of amplification. For $A_{F_O-S}^T$, $T_{N_S}^*$ for all records is less than the designated period of 1.5 s. Therefore, as $S_a$ and $T_{N_S}^*$ increase, amplification mildly increase due to resonance indicating mechanism B is controlling. Finally peak amplification, $A_F^P$ always occurs at $T_{N_S}^*$ and migration of site period is not relevant. For $A_F^P$, nonlinearity is controlled only by mechanism A. As a result, amplification mildly reduces as $S_a$ increases. The widely accepted notion, incorporated in building codes, suggests amplification factor reduces with shaking intensity due to nonlinear soil behavior. Different trends described above indicate the impact of “shaking intensity” is complex; amplification may increase with shaking intensity when site period shifts toward period of interest.

4.3. Depth-dependency of amplification-shaking intensity ($AF-S_a$) Models

Plotted in Fig. 5(a), (b) and (c) are amplification factor, $AF$, at periods of 0.1 s, 0.6 s, and 1.0 s, respectively, versus bedrock spectral acceleration, $S_a$, at corresponding periods for sand profiles with $V_S = 200$ m/s and depths to bedrock of 25 m, 50 m, and 75 m. Peak amplification factor, $A_F$, is plotted versus bedrock spectral acceleration at site fundamental period, $S_a^F$, in Fig. 5(d). Note that while data point clusters corresponding to different depths are visually separated in Fig. 5(a), (b) and (c), data points of different depths for peak amplification are intermixed in Fig. 5(d). For each soil profile, the best fitted quadratic or bi-linear function (in log scale) is also plotted following Bazzurro and Cornell (2004). Fitted curves for depth to bedrock of 25 m, 50 m and 75 m are distinct in Fig. 5(a), (b) and (c) suggesting amplification versus shaking intensity ($AF-S_a$) models are depth-dependent at periods of 0.1 s, 0.6 s and 1.0 s. Note, however, a depth-independent model seems appropriate for peak amplification.

To statistically test this observation, we computed the residual standard deviation of amplification factor, $\sigma_{e_A(DF)}$, after accounting for its dependence on $S_a$. $\sigma_{e_A(DF)}$ represents the random “record-to-record” variability of amplification factor and can be computed using the following equation:

$$\sigma_{e_A(DF)} = \sqrt{1 - R^2} \cdot \sigma_{e(DF)}$$

(3)

where $\sigma_{e(DF)}$ is the standard deviation of amplification factor calculated from 74 records for each profile at designated period and, $R^2$ is...
the coefficient of determination computed for AF versus \( S_a \). Presented in Table 2 are \( \sigma_{Af(AF)} \) values based on using two sets of \( R^2 \) values obtained from depth-specific and depth-independent \( AF-S_a \) models. Note the following trends:

- \( \sigma_{Af(AF)} \) based on depth-independent model is larger than the corresponding value computed using the depth-specific models. For example, for sand with \( V_s = 200 \) m/s, \( \sigma_{Af(AF)} \) for depth-independent model is \( 1.5–3 \) times larger than \( \sigma_{Af(AF)} \) based on depth-specific models. Depth-independent models generate a large uncertainty which is epistemic in nature, that is, can be removed if model takes into account the depth effects.
- \( \sigma_{Af(AF)} \) for peak amplification is similar using either models ranging from 0.04 to 0.12.
- Similar to findings of Bazzurro and Cornell (2004), \( \sigma_{Af(AF)} \) at long period is relatively small ranging from 0.03 to 0.13.
- \( \sigma_{Af(AF)} \) ranges from 0.06 to 0.34 at short and mid periods which generally agrees with \( \sigma_{Af(AF)} \) range of less than 0.3 reported by Bazzurro and Cornell [4].
- Bazzurro and Cornell [4] study was performed on two specific sites. These results verify and extend their findings to a broader range of soil and site conditions.

### 4.4. Strain compatible site period, a prospective parameter

It was shown that site period shift in nonlinear strain range can have a critical impact on site response. None of the currently proposed site or motion parameters in the scope of single proxy approach properly captures this effect. In our search, we found strain compatible site period, \( T_{N*} \), a promising parameter that holds key predictive information including “shaking intensity”, “site period” and “site period shift”.

SHAKE2000 computes strain compatible shear wave velocity, \( V_{S*} \), for each sub-layer from calculated shear strain at the end of iteration in equivalent-linear method and using \( G/G_{MAX} \) curves. \( V_{S*} \) is then averaged from sublayers to compute \( V_{S*} \) and \( T_{N*} \) \( = \) \( 4 \) \( H/ V_{S*} \) for soil column. For the purpose of this study, \( T_{N*} \), was provided for each record by SHAKE2000. Plotted in Fig. 6(a) through (d) are amplification factors at periods of 0.1 s, 0.6 s, 1.0 s and 3.0 s versus \( T_{N*} \). Each plot includes data from 19 profiles excited by 74 motions producing 1406 data points. Also plotted are mean amplification factors for each soil profile averaged from 74 records, \( AF_{m}, \) using red solid circle marker. These plots put various components that contribute in site response in a holistic prospective. Three major components drive site response including \( T_{N*} \), \( V_S \) and damping. The following trends can be identified based on these components:

#### 4.5. \( V_S \)-based trend

A visual examination of data clusters of different profiles at 0.1 s, 0.6 s, and 1.0 s shows that for a similar \( T_{N*} \) data points corresponding to profiles with lower \( V_S \) tend to fall above data clusters with higher \( V_S \). This observation is another expression of the trend identified for amplification factor as a function of \( V_S \) in Eqs. (1) and (2).

#### 4.6. \( T_{N*} \)-based Trend

Note that in each plot amplification factor peaks when site period matches period of interest. Amplification at 0.1 s steadily decreases as \( T_{N*} \) shifts away from 0.1 s. Amplification at 0.6 s shows two peaks at 0.6 s and 1.8 s corresponding to the first and the second fundamental site period. Amplification at 1.0 s peaks at 1.0 s. Amplification at 3.0 s steadily increases as \( T_{N*} \) approaches 3.0 s. These trends can be explained by resonance.

We used the mean amplification factors, \( AF_{m} \), each representing the average site response from 74 records for a single site to generate amplification factor versus \( T_{N*} \) trend curves. Before generating trend curve, \( AF_{m} \) values were normalized to remove \( V_S \) effects by applying a correction factor based on Eqs. (1) and (2). For example, \( AF_{m} \) at 0.6 s for profile S-75–400 (\( V_S = 400 \) m/s) is 1.20. To compute amplification factor for \( V_S = 300 \) m/s, we used Eq. (2) (generic sand) which provides \( AF_{m*} \), equal to 1.96 and 2.20 for \( V_S = 400 \) m/s and \( V_S = 300 \) m/s, respectively. The conversion factor (in natural log scale) is calculated as \( \ln \) (2.20) – \( \ln \) (1.96) = 0.12. The corrected amplification factor for \( V_S = 300 \) m/s is then computed as \( \exp \) (1.96 + 0.12) = 1.35. Using similar method, three sets of \( AF_{m} \) values for \( V_S = 200 \) m/s, 300 m/s, and 400 m/s were generated. A trend curve was then manually drawn for each \( AF_{m} \) set. Amplification factors at 3.0 s do not show a clear dependency on \( V_S \), therefore, a single curve was plotted without adjusting for \( V_S \). However, our relatively shallow soil profiles may
not allow seeing the dependency of long-period amplification on $V_N$. It is likely that amplification at long period would depend on $V_N$ in deep sites where depth is large compared to wavelength.

Amplification factors from individual records also follow similar trend lines set by mean amplification factors; for each soil profile, $AF$ increase as $T_N^*$ approaches period of interest, and decrease as $T_N^*$ shifts away from period of interest. This indicates $T_N^*$ not only holds predictive information about average response of different soil profiles but also record-to-record variation of response for a given soil profile.

4.7. Damping-based trend

In each plot a damping-controlled zone is identified in which data points show a larger scatter around $T_N^*$-based trend line set by mean amplification factors. This zone includes the range of $T_N^*$ > period of interest in each plot; that is, $0.1 \text{s} < T_N^*$ in Fig. 6(a), $0.6 \text{s} < T_N^*$ in Fig. 6(b), and $1.0 \text{s} < T_N^*$ in Fig. 6(c). In damping control zone, $AF$ reduces as $T_N^*$ increases following a steeper slope than the slope of the $T_N^*$-based curve set by mean amplification factors. In damping-controlled zone as $T_N^*$ shifts away from resonance period, damping increase and site period shift [nonlinearity mechanisms A and B discussed in previous section] concurrently de-amplify the motion resulting in a sharp reduction of amplification factor.

We used a method that is schematically illustrated in Fig. 7 to quantify damping effects. According to this method, when $T_N^*$ < period of interest, amplification factor can be directly read from $T_N^*$-based trend line. When $T_N^*$ > period of interest; first, the mean amplification factor for soil profile, $AF_{m}$, is computed by the $T_N^*$-based curve, then, amplification factor for a specific record is corrected for damping using amplification-shaking intensity ($AF$-$SA$) relationships. We plotted $AF$ versus $SA$ at periods of 0.1, 0.6, and 1.0 s (similar to Fig. 5). The best fitted model is quadratic[4] and can alternatively be modeled as bilinear with two distinct slopes $b_1$ for $SA < S_{um}$, and $b_2$ for $SA > S_{um}$, where $S_{um}$ is the spectral acceleration averaged from 74 records. For records included in our dataset, $S_{um}$ is $0.19 g, 0.12 g$, and $0.09 g$, for periods of 0.0 s (PGA), 0.6 s, and 1.0 s, respectively. We assumed the mean amplification factor, $AF_{m}$, obtained from $T_N^*$-based curve corresponds to $SA_{m}$ of approximately $0.1 g$. For $SA$ greater or smaller than $SA_{m}$, $AF$ should be corrected to account for damping using the following equations:

$$\ln(AF_{sa}) = \ln(AF_{m}) + \Delta \ln(AF_{m})$$

(4)

where $AF_{sa}$ is the amplification factor corresponding to specific record with shaking intensity of $SA$. Mean amplification, $AF_{m}$, is computed

NC$^2$ Not calculated

$^*$ Not sufficient data to compute $b$ values

For AAP, and for VS=400 m/s, AF-SA relationships show a very weak correlation resulting in approximately b1=b2 =0.

from $T_{N^*}$-based curve for $S_{uvmin}$ =0.1g in Fig. 6, and:

$$\Delta \ln(AF_{SA}) = b \cdot [\ln(S_v) - \ln(S_{uvmin})]$$  \hspace{1cm} (5)

where

$$b = b_1 \text{ for } S_v < S_{uvmin} \text{ and } b = b_2 \text{ for } S_v > S_{uvmin}$$  \hspace{1cm} (6)

Step 1: Determine site parameters including $V_S$, depth to bedrock (H), and site period, $T_N$ (=4H/$V_S$).

Step 2: Determine motion parameters including spectral acceleration of ground motion at 0.0 s (PGA), 0.6 s, and 1.0 s

Step 3: Estimate strain compatible site period, $T_{N^*}$. It was mentioned that SHAKE2000 provided $T_{N^*}$ for each profile and each record. For profiles included in our dataset, we found $V_S$ and spectral acceleration at site period, $S_P$, are strongly correlated with coefficients of determination $R^2$ mostly above 0.8. Plotted in Fig. 8 are $V_S$ versus $S_P$ for generic sand and clay and $V_S$ =400 m/s and 200 m/s. Use interpolation to estimate $V_S$ for other values of depth to bedrock and $V_S$. Note two sets of strain compatible site period should be computed:

- Use Fig. 8 and $S_d =0.1g$ to estimate mean strain compatible site period, $T_{N^*}$
- Use Fig. 8 and $S_d =S_d^{*F}$ (spectral acceleration at site period for ground motion of interest) to compute strain compatible site period, $T_{N^*}$

Step 4: Compute amplification factor at periods of 0.1 s, 0.6 s, 1.0 s and 3.0 s Use Fig. 6 to first estimate mean amplification factor. Use method shown in Fig. 7 to correct for damping. If $T_{N^*}$ < period of interest, no damping correction is required.

Step 5: Compute peak amplification factor. Maximum amplification factor across period range, $A_{F_p}$, which occurs at site period, $T_{N^*}$, can be estimated in two steps: 1) use Eqs. (1) and (2) to predict the mean value of peak amplification factor (averaged from 74 records), 2) use Table 3 to find $b_1$ or $b_2$, use Eq. (4) through 6 to correct for damping effects. This procedure is schematically shown in Fig. 9. Note the input spectral acceleration in Fig. 9(b) is spectral acceleration of bedrock at site period.

This procedure provides amplification factors at periods of 0.1 s, 0.6 s, 1.0 s, 3.0 s, and also peak amplification factor to create a five-point estimate of transfer function. Interpolation can be used to compute amplification at intermediate periods. The proposed procedure can be conveniently implemented in spreadsheet. The application of proposed procedure would be subject to limitations of the methodology and range of soil conditions used in this study.

4.9. Example

Strong amplification of ground motion due to underlying thick clay deposits was widely observed in city of Oakland during the 1989 Loma Prieta earthquake [25]. The proposed procedure was tested for the case of Oakland 2-story building site [25]. We used the outcrop rock motion recorded at the nearby Yerba Buena Island station (90 deg) as input motion. The 5% damped response spectra of the outcrop motion and

**Fig. 8.** Strain compatible shear wave velocity versus spectral acceleration, (a) Sand, depth to bedrock 25 m, (b) Sand, depth to bedrock 75 m, (c) Clay, depth to bedrock 25 m, (d) Clay, depth to bedrock 75 m.
on top of layer 5 from Analysis I was applied as input motion to base of layer No. 4 and propagated through sublayers 1 through 4 (assuming average \( V_S = 197 \text{ m/s} \)) to calculate response at the ground surface. Considering majority of underlying soils consist of clay or sandy clay, we used the generic clay model.

The detailed calculation steps and intermediate parameters computed in simplified procedure are summarized in Table 5. The calculated response using simplified procedure along with the calculated response using SHAKE by Sun et al. [25] are plotted in Fig. 10. The surface response spectra estimated based on simplified procedure agrees well with SHAKE results and both methods generally provide a reasonable estimation of surface response represented by two recorded surface motions. The simplified procedure underestimates the response at very short period which can be attributed to over-simplification of soil profile. Also note that the simplified procedure provides a better estimate of amplification than SHAKE at proximity of 1.0 s. In general, the discrepancy between simplified procedure and recorded motions can be a result of the selection of input rock motions, limitations of the one-dimensional model, limitation of equivalent-linear method, idealization of soil profile, and unaccounted soil-structure interaction effects.

5. Conclusions

1. Single proxy approach is widely used to estimate the effect of near surface soils on seismic demand. Numerous studies have investigated merits of proposed proxies including shear wave velocity (\( V_S \)) averaged in top 30 m and site period with some contradicting results. This has left the debate over selecting the best “site proxy” unsettled.
2. We used a methodology that allowed isolating and tracking the impact of components that drive site response including \( V_S \), site period, and shaking intensity. We performed a parametric study on 19 hypothetical shallow profiles each shaken by 74 records from 27 earthquakes using one-dimensional equivalent-linear method. The results were analyzed to identify trends.
3. The effect of \( V_S \) on site response was quantified by tracking maximum amplification factor across the period range, averaged from 74 records for each soil profile. Soil type-specific relationships were developed for amplification as a function of \( V_S \).
4. Nonlinear soil behavior impacts site response through two mechanisms: “damping increase” which de-amplifies the motion; and “migration of site period” which may amplify or de-amplify the motion depending on the direction of site period shift with respect to period of interest. Amplification factor at a given period increases with shaking intensity when site period migrates towards period of interest.

Step 1: Determine Site Parameters

- Motion Parameters
  - PGA (g) = 0.08
  - Ss, 1.0 s (g) = 0.09
  - Ss, f* (g) = 0.25

Step 2: Determine Motion Parameters

- Step 3: Determine Site Compatible Parameters
  - Vgs/Vs = 0.91
  - Tg* (s) = 0.76

Step 3: Determine Site Compatible Parameters

- Site Period
  - Vsm/ Vs = 0.96
  - Tm (s) = 0.71

Step 4: Determine Amplification factor and damping correction

- Mean Amplification factor
  - Mean AFo,1 = 1.0
  - Mean AFo,6 = 1.45

- Mean damping correction
  - Mean AFo,1 = 1.7
  - Mean AFo,6 = 1.2

- 0.1 s
  - b values for damping correction
    - Mean AFo,1 = 1.7
    - Mean AFo,6 = 1.2

Damping correction not required

because Tg* < 1.0 s

Step 5: Compute Peak Amplification Factor

- AFmax = 1.94

- AFp = 1.90

b values for damping correction

- bp = -0.02 for Analysis No. 1
- bp = -0.05 for Analysis No. 2

5. Depth-specific and depth-independent models were analyzed for amplification versus shaking intensity. We found the residual standard deviation of amplification factor, σlat(AFp), using a depth-independent model are up to three times larger than σlat(AFp) based on depth-specific model. Using a depth-independent model generates additional uncertainty which is epistemic in nature, that is, can be removed provided that suitable models are used.

6. σlat(AFp) ranges from 0.06 to 0.34 at short and mid periods, 0.03–0.13 at long period, and 0.04–0.12 for peak amplification factor. These results generally match the σlat(AFp) range of less than 0.3 reported by Bazzurro and Cornell [4] based on two soil profiles.

7. Plots of amplification versus strain compatible site period provide a holistic prospective of how Vg, strain compatible site period, and damping contribute in site response. These three components contain mutually exclusive predictive information regarding site response. Trend lines were presented for different Vg values to estimate amplification factor as a function of strain compatible site period at different periods. A method was presented to correct amplification factor for damping effects.

8. A simplified procedure is proposed to address the need in current state of practice for an intermediate site response solution between the rigorous numerical solutions on one end and the generic site factors on the other end. We applied the proposed procedure to a building site shaken by Loma Prieta (1989) earthquake. The predicted amplification factors match reasonably well with recorded motion at the surface and also one-dimensional site response analysis by SHAKE.
